Preface to the Second Edition

In preparing the first edition of the *Encyclopedia of Systems and Control*, we, the editors, were faced with the daunting task of organizing a discipline with deep roots and a wide footprint. To help with the undertaking, we were fortunate that leading experts from around the world agreed to serve as section editors. Our initial goal of about 200 articles was substantially exceeded, and the first edition featured 250 contributions in 30 parts – covering both theoretical and application-oriented topics.

In the several years since the first edition was published, we have been gratified by the recognition of the work and its usage. But systems and control is a dynamic discipline. Notable advances have occurred within the topics covered in the first edition. Moreover, new areas have emerged where synergy with control is being recognized and exploited. Indeed, as we reflect on a project that has now extended over almost a decade, we are struck by the increasingly cross-disciplinary currents that are influencing the directions of research in the field while also being guided by its mathematical underpinnings.

The vitality of systems and control as a discipline is evident in the additions to this second edition. Once again our goal, this time of about 50 new articles, was overachieved. With 366 articles in 39 parts, it would take a leap year of reading an article a day to exhaust the material in the new book! In addition to updates from the first edition, new topics include biomedical devices, building control, CPS/IoT, human-in-the-loop control, machine learning, control of micro and nano systems, quantum control, and vision-based control. As with the first edition, the current edition aims to make the vast array of topics that are now considered part of systems and control accessible to everyone who needs an introduction and also provides extensive pointers to further reading.

We continue to owe an enormous debt to major intellectual leaders in the field who agreed to serve as topical section editors (the list appears on the following pages). They have recruited teams of experts as authors and have managed extensive peer review of everything that appears in these volumes. We once again wish to express our gratitude to the many professionals at Springer who have supported the encyclopedia, notably Oliver Jackson, Andrew Spencer, and Vasowati Shome. We hope readers find this second edition of the encyclopedia a useful and valuable compendium for a discipline that is central to our technologically driven world today.

Preface to the First Edition

The history of Automatic Control is both ancient and modern. If we adopt the broad view that an automatic control system is any mechanism by which an input action and output action are dynamically coupled, then the origins of this encyclopedia's subject matter may be traced back more than 2,000 years to the era of primitive time-keeping and the clepsydra water clock perfected by Ctesibius of Alexandria. In more recent history, frequently cited examples of feedback control include the automatically refilling reservoirs of flush toilets (perfected in the late nineteenth century) and the celebrated flyball steam-flow governor described in J.C. Maxwell's 1868 Royal Society of London paper – "On Governors."

Although it is useful to keep the technologies of antiquity in mind, the history of systems and control as covered in the pages of this encyclopedia begins in the twentieth century. The history was profoundly influenced by work of Nyqvist, Black, Bode, and others who were developing amplifier theory in response to the need to transmit wireline signals over long distances. This research provided major conceptual advances in feedback and stability that proved to be of interest in the theory of servomechanisms that was being developed at the same time. Driven by the need for fast and accurate control of weapons systems during World War II, automatic control developed quickly as a recognizable discipline.

While the developments of the first half of the twentieth century are an important backdrop for the *Encyclopedia of Systems and Control*, most of the topics directly treat developments from 1948 to the present. The year 1948 was auspicious for systems and control – and indeed for all the information sciences. Norbert Wiener's book *Cybernetics* was published by Wiley, the transistor was invented (and given its name), and Shannon's seminal paper "A Mathematical Theory of Communication" was published in the *Bell System Technical Journal*. In the years that followed, important ideas of Shannon, Wiener, Von Neumann, Turing, and many others changed the way people thought about the basic concepts of control systems. The theoretical advances have propelled industrial and societal impact as well (and vice versa). Today, advanced control is a crucial enabling technology in domains as numerous and diverse as aerospace, automotive, and marine vehicles; the process industries and manufacturing; electric power systems; homes and buildings; robotics; communication networks; economics and finance; and biology and biomedical devices.

It is this incredible broadening of the scope of the field that has motivated the editors to assemble the entries that follow. This encyclopedia aims to help students, researchers, and practitioners learn the basic elements of a vast array of topics that are now considered part of systems and control. The goal is to provide entry-level access to subject matter together with cross-references to related topics and pointers to original research and source material.

Entries in the encyclopedia are organized alphabetically by title, and extensive links to related entries are included to facilitate topical reading – these links are listed in “Cross-References” sections within entries. All crossreferenced entries are indicated by a preceding symbol: ►. In the electronic version of the encyclopedia these entries are hyperlinked for ease of access.

The creation of the *Encyclopedia of Systems and Control* has been a major undertaking that has unfolded over a 3-year period. We owe an enormous debt to major intellectual leaders in the field who agreed to serve as topical section editors. They have ensured the value of the opus by recruiting leading experts in each of the covered topics and carefully reviewing drafts. It has been a pleasure also to work with Oliver Jackson and Andrew Spencer of Springer, who have been unfailingly accommodating and responsive over this time.

As we reflect back over the course of this project, we are reminded of how it began. Gary Balas, one of the world’s experts in robust control and aerospace applications, came to one of us after a meeting with Oliver at the Springer booth at a conference and suggested this encyclopedia – but was adamant that he wasn’t the right person to lead it. The two of us took the initiative (ultimately getting Gary to agree to be the section editor for the aerospace control entries). Gary died last year after a courageous fight with cancer. Our sense of accomplishment is infused with sadness at the loss of a close friend and colleague.

We hope readers find this encyclopedia a useful and valuable compendium and we welcome your feedback.

John Baillieul
Tariq Samad

List of Topics

Adaptive Control

Section Editor: *Richard Hume Middleton*

Adaptive Control of Linear Time-Invariant Systems
Adaptive Control: Overview
Autotuning
Extremum Seeking Control
History of Adaptive Control
Iterative Learning Control
Model Reference Adaptive Control
Nonlinear Adaptive Control
Robust Adaptive Control
Switching Adaptive Control

Aerospace Applications

Section Editor: *Panagiotis Tsiotras*

Air Traffic Management Modernization:
 Promise and Challenges
Aircraft Flight Control
Inertial Navigation
Pilot-Vehicle System Modeling
Satellite Control
Space Robotics
Spacecraft Attitude Determination
Tactical Missile Autopilots
Trajectory Generation for Aerial Multicopters
Unmanned Aerial Vehicle (UAV)

Automotive and Road Transportation

Section Editor: *Luigi Glielmo*

Adaptive Cruise Control
Automated Truck Driving
Connected and Automated Vehicles

Engine Control

Fuel Cell Vehicle Optimization and Control
Lane Keeping Systems
Motorcycle Dynamics and Control
Powertrain Control for Hybrid-Electric and Electric Vehicles
Transmissions
Vehicle Dynamics Control

Biomedical Devices

Section Editor: *B. Wayne Bequette*

Automated Anesthesia Systems
Automated Insulin Dosing for Type 1 Diabetes
Control of Anemia in Hemodialysis Patients
Control of Left Ventricular Assist Devices

Biosystems and Control

Section Editor: *Elisa Franco*

Control of Drug Delivery for Type 1 Diabetes Mellitus
Deterministic Description of Biochemical Networks
Identification and Control of Cell Populations
Modeling of Pandemics and Intervention Strategies: The COVID-19 Outbreak
Monotone Systems in Biology
Reverse Engineering and Feedback Control of Gene Networks
Robustness Analysis of Biological Models
Scale-Invariance in Biological Sensing
Spatial Description of Biochemical Networks
Stochastic Description of Biochemical Networks

Structural Properties of Biological and Ecological Systems
Synthetic Biology

Building Control

Section Editor: *John T. Wen*

Building Comfort and Environmental Control
Building Control Systems
Building Energy Management System
Building Fault Detection and Diagnostics
Building Lighting Systems
Control of Circadian Rhythms and Related Processes
Emergency Building Control
Facility Control and Optimization Problems in Data Centers
Human-Building Interaction (HBI)
Vibration Control System Design for Buildings

Classical Optimal Control

Section Editor: *Michael Cantoni*

Characteristics in Optimal Control Computation
Finite-Horizon Linear-Quadratic Optimal Control with General Boundary Conditions
H₂ Optimal Control
L1 Optimal Control
Linear Matrix Inequality Techniques in Optimal Control
Linear Quadratic Optimal Control
Numerical Methods for Nonlinear Optimal Control Problems
Optimal Control and Pontryagin's Maximum Principle
Optimal Control and the Dynamic Programming Principle
Optimal Control via Factorization and Model Matching
Optimal Sampled-Data Control

Complex Systems with Uncertainty

Section Editor: *Fabrizio Dabbene*

Computational Complexity in Robustness Analysis and Design
Consensus of Complex Multi-agent Systems

Controlling Collective Behavior in Complex Systems
Dynamical Social Networks
Markov Chains and Ranking Problems in Web Search
Randomized Methods for Control of Uncertain Systems
Stability and Performance of Complex Systems Affected by Parametric Uncertainty
Stock Trading via Feedback Control Methods
Uncertainty and Robustness in Dynamic Vision

Computer-Aided Control Systems Design

Section Editor: *Andreas Varga*

Basic Numerical Methods and Software for Computer Aided Control Systems Design
Computer-Aided Control Systems Design: Introduction and Historical Overview
Descriptor System Techniques and Software Tools
Fault Detection and Diagnosis: Computational Issues and Tools
Interactive Environments and Software Tools for CACSD
Matrix Equations in Control
Model Building for Control System Synthesis
Model Order Reduction: Techniques and Tools
Multi-domain Modeling and Simulation
Optimization-Based Control Design Techniques and Tools
Robust Synthesis and Robustness Analysis Techniques and Tools
Validation and Verification Techniques and Tools

Control of Manufacturing Systems

Section Editor: *Dawn Tilbury*

Control of Additive Manufacturing
Control of Machining Processes
Programmable Logic Controllers
Run-to-Run Control in Semiconductor Manufacturing
Statistical Process Control in Manufacturing
Stream of Variations Analysis

Control of Marine Vessels

Section Editor: *Kristin Y. Pettersen*

Advanced Manipulation for Underwater Sampling
 Control of Networks of Underwater Vehicles
 Control of Ship Roll Motion
 Dynamic Positioning Control Systems for Ships and Underwater Vehicles
 Mathematical Models of Marine Vehicle-Manipulator Systems
 Mathematical Models of Ships and Underwater Vehicles
 Motion Planning for Marine Control Systems
 Underactuated Marine Control Systems

Control of Networked Systems

Section Editor: *Jorge Cortés*

Averaging Algorithms and Consensus
 Controllability of Network Systems
 Distributed Estimation in Networks
 Distributed Optimization
 Dynamic Graphs, Connectivity of Estimation and Control over Networks
 Flocking in Networked Systems
 Graphs for Modeling Networked Interactions
 Multi-vehicle Routing
 Nash Equilibrium Seeking over Networks
 Networked Systems
 Optimal Deployment and Spatial Coverage
 Oscillator Synchronization
 Privacy in Network Systems
 Routing in Transportation Networks
 Vehicular Chains

Control of Process Systems

Section Editor: *Sebastian Engell*

Control and Optimization of Batch Processes
 Control Hierarchy of Large Processing Plants: An Overview
 Control of Biotechnological Processes
 Control Structure Selection
 Controller Performance Monitoring
 Industrial MPC of Continuous Processes
 Model-Based Performance Optimizing Control

Multiscale Multivariate Statistical Process Control
 PID Control
 Real-Time Optimization of Industrial Processes
 Scheduling of Batch Plants
 State Estimation for Batch Processes

CPS / IoT

Section Editor: *Karl H. Johansson*

Controller Synthesis for CPS
 Cyber-Physical Maritime Robotic Systems
 Cyber-Physical Security
 Cyber-Physical-Human Systems
 Industrial Cyber-Physical Systems
 Medical Cyber-Physical Systems: Challenges and Future Directions

Discrete-Event Systems

Section Editor: *Christos G. Cassandras*

Applications of Discrete Event Systems
 Diagnosis of Discrete Event Systems
 Discrete Event Systems and Hybrid Systems, Connections Between
 Modeling, Analysis, and Control with Petri Nets
 Models for Discrete Event Systems: An Overview
 Opacity of Discrete Event Systems
 Perturbation Analysis of Discrete Event Systems
 Perturbation Analysis of Steady-State Performance and Relative Optimization
 Supervisory Control of Discrete-Event Systems

Distributed Parameter Systems

Section Editor: *Miroslav Krstic*

Adaptive Control of PDEs
 Backstepping for PDEs
 Bilinear Control of Schrödinger PDEs
 Boundary Control of 1-D Hyperbolic Systems
 Boundary Control of Korteweg-de Vries and Kuramoto-Sivashinsky PDEs
 Control of Fluid Flows and Fluid-Structure Models
 Control of Linear Systems with Delays
 Control of Nonlinear Systems with Delays

Input-to-State Stability for PDEs

Motion Planning for PDEs

Economic and Financial Systems

Section Editor: *Rene Carmona*

Cash Management

Credit Risk Modeling

Financial Markets Modeling

Inventory Theory

Investment-Consumption Modeling

Option Games: The Interface Between Optimal
Stopping and Game Theory

Electric Energy Systems

Section Editor: *Joe Chow*

Active Power Control of Wind Power Plants
for Grid Integration

Cascading Network Failure in Power Grid
Blackouts

Coordination of Distributed Energy Resources
for Provision of Ancillary Services:
Architectures and Algorithms

Demand Response: Coordination of Flexible
Electric Loads

Electric Energy Transfer and Control via Power
Electronics

Lyapunov Methods in Power System Stability

Model Predictive Control for Power Networks

Power System Voltage Stability

Small Signal Stability in Electric Power Systems

Time-Scale Separation in Power System Swing
Dynamics: Singular Perturbations
and Coherency

Wide-Area Control of Power Systems

Estimation and Filtering

Section Editor: *Yaakov Bar-Shalom*

Bounds on Estimation

Data Association

Estimation for Random Sets

Estimation, Survey on

Extended Kalman Filters

Kalman Filters

Nonlinear Filters

Particle Filters

Frequency-Domain Control

Section Editor: *J. David Powell*

Classical Frequency-Domain Design
Methods

Control System Optimization Methods in the
Frequency Domain

Frequency-Response and Frequency-Domain
Models

Polynomial/Algebraic Design Methods

Quantitative Feedback Theory

Spectral Factorization

Game Theory

Section Editor: *Tamer Başar*

Auctions

Cooperative Solutions to Dynamic Games

Dynamic Noncooperative Games

Evolutionary Games

Game Theory for Security

Game Theory: A General Introduction and
a Historical Overview

Learning in Games

Linear Quadratic Zero-Sum Two-Person
Differential Games

Mean Field Games

Mechanism Design

Network Games

Pursuit-Evasion Games and Zero-Sum

Two-Person Differential Games

Stochastic Games and Learning

Strategic Form Games and Nash

Equilibrium

Geometric Optimal Control

Section Editor: *Anthony Bloch*

Discrete Optimal Control

Optimal Control and Mechanics

Optimal Control with State Space
Constraints

Singular Trajectories in Optimal Control

Sub-Riemannian Optimization

Synthesis Theory in Optimal
Control

Human-in-the-Loop Control

Section Editor: *Tariq Samad*

Adaptive Human Pilot Models for Aircraft Flight Control

Human Decision-Making in Multi-agent Systems

Interaction Patterns as Units of Analysis in Hierarchical Human-in-the-Loop Control

Trust Models for Human-Robot Interaction and Control

Hybrid Systems

Section Editor: *Françoise Lamnabhi-Lagarigue*

Event-Triggered and Self-Triggered Control

Formal Methods for Controlling Dynamical Systems

Hybrid Dynamical Systems, Feedback Control of

Hybrid Model Predictive Control

Hybrid Observers

Modeling Hybrid Systems

Nonlinear Sampled-Data Systems

Output Regulation Problems in Hybrid Systems

Safety Guarantees for Hybrid Systems

Simulation of Hybrid Dynamic Systems

Stability Theory for Hybrid Dynamical Systems

Identification and Modeling

Section Editor: *Lennart Ljung*

Deep Learning in a System Identification Perspective

Experiment Design and Identification for Control

Frequency Domain System Identification

Identification of Network Connected Systems

Modeling of Dynamic Systems from First Principles

Nonlinear System Identification Using Particle Filters

Nonlinear System Identification: An Overview of Common Approaches

Nonparametric Techniques in System Identification

Nonparametric Techniques in System Identification: The Time-Varying and Missing Data Cases

Subspace Techniques in System Identification

System Identification Software

System Identification Techniques:

Convexification, Regularization, Relaxation

System Identification: An Overview

Use of Gaussian Processes in System Identification

Information-Based Control

Section Editor: *Wing Shing Wong*

Cyber-Physical Systems Security:

A Control-Theoretic Approach

Data Rate of Nonlinear Control Systems and Feedback Entropy

Information and Communication Complexity of Networked Control Systems

Information-Based Multi-agent Systems

Information-Theoretic Approaches for

Non-classical Information Patterns

Motion Description Languages and

Symbolic Control

Networked Control Systems: Architecture and Stability Issues

Networked Control Systems: Estimation and Control over Lossy Networks

Noisy Channel Effects on Multi-agent Consensus

Quantized Control and Data Rate Constraints

Intelligent Control

Section Editor: *Thomas Parisini*

Approximate Dynamic Programming (ADP)

Fault Detection and Diagnosis

Fault-Tolerant Control

Learning Theory: The Probably Approximately Correct Framework

Neuro-inspired Control

Stochastic Fault Detection

Linear Systems Theory (Time-Domain)

Section Editor: *Panos J Antsaklis*

Controllability and Observability

Linear State Feedback

Linear Systems: Continuous-Time Impulse Response Descriptions

Linear Systems: Continuous-Time, Time-Invariant State Variable Descriptions

Linear Systems: Continuous-Time,
Time-Varying State Variable Descriptions
Linear Systems: Discrete-Time Impulse
Response Descriptions
Linear Systems: Discrete-Time, Time-Invariant
State Variable Descriptions
Linear Systems: Discrete-Time, Time-Varying,
State Variable Descriptions
Observer-Based Control

Active Power Control of Wind Power Plants for Grid Integration

Lucy Y. Pao
University of Colorado, Boulder, CO, USA

Abstract

Increasing penetrations of intermittent renewable energy sources, such as wind, on the utility grid have led to concerns over the reliability of the grid. One approach for improving grid reliability with increasing wind penetrations is to actively control the real power output of wind turbines and wind power plants. Providing a full range of responses requires derating wind power plants so that there is headroom to both increase and decrease power to provide grid balancing services and stabilizing responses. Results thus far indicate that wind turbines may be able to provide primary frequency control and frequency regulation services more rapidly than conventional power plants.

Keywords

Active power control · Automatic generation control · Frequency regulation · Grid balancing · Grid integration · Primary frequency control · Wind energy

Introduction

Wind penetration levels across the world have increased dramatically, with installed capacity growing at a mean annual rate of 17% over the last decade (Broehl and Asmus 2018). Some nations in Western Europe, particularly Denmark, Ireland, Portugal, Spain, the United Kingdom, and Germany, have seen wind provide more than 18% of their annual electrical energy needs (Wiser and Bolinger 2018). To maintain grid frequency at its nominal value, the electrical generation must equal the electrical load on the grid. This balancing has historically been left up to conventional utilities with synchronous generators, which can vary their active power output by simply varying their fuel input. Grid frequency control is performed across a number of regimes and time scales, with both manual and automatic control commands. Further details can be found in Diaz-Gonzalez et al. (2014) and Ela et al. (2011).

Wind turbines and wind power plants are recognized as having the potential to meet demanding grid stabilizing requirements set by transmission system operators (Ela et al. 2011; Aho et al. 2013a, b; Diaz-Gonzalez et al. 2014; Ela et al. 2014; Fleming et al. 2016). Recent grid code requirements have spurred the development of wind turbine active power control (APC) systems (Diaz-Gonzalez et al. 2014), in some cases mandating wind turbines to participate in

grid frequency regulation and provide stabilizing responses to changes in grid frequency. The ability of wind turbines to provide APC services also allows them to follow forecast-based power production schedules.

For a wind turbine to fully participate in grid frequency control, it must be derated (to P_{derated}) with respect to the maximum power (P_{max}) that can be generated given the available wind, allowing for both increases and decreases in power, if necessary. Wind turbines can derate their power output by pitching their blades to shed aerodynamic power or reducing their generator torque in order to operate at higher-than-optimal rotor speeds. Wind turbines can then respond at different time scales to provide more or less power through pitch control (which can provide a power response within seconds) and generator torque control (which can provide a power response within milliseconds) (Aho et al. 2016).

Wind Turbine Inertial and Primary Frequency Control

Inertial and primary frequency control is generally considered to be the first 5–30 s after a frequency event occurs. In this regime, the governors of capable generators actuate, allowing for a temporary increase or decrease in the utilities' power outputs. The primary frequency control (PFC) response provided by conventional synchronous generators can be characterized by a droop curve, which relates fluctuations in grid frequency to a change in power from the utility. For example, a 3% droop curve means that a 3% change in grid frequency yields a 100% change in commanded power.

Although modern wind turbines do not inherently provide inertial or primary frequency control responses because their power electronics impart a buffer between their generators and the grid, such responses can be produced through careful design of the wind turbine control systems. While the physical properties of a conventional synchronous generator yield a static droop characteristic, a wind turbine can be controlled to provide a primary frequency response via either a static or time-varying droop curve.

A time-varying droop curve can be designed to be more aggressive when the magnitude of the rate of change of frequency of the grid is larger.

Figure 1 shows a simulation of a grid response under different scenarios when 5% of the generating capacity suddenly goes offline. When the wind power plant (10% of the generation on the grid) is operating with its normal baseline control system that does not provide APC services, the frequency response is worse than the no-wind scenario, due to the reduced amount of conventional generation in the wind-baseline scenario that can provide power control services. However, compared to both the no-wind and wind-baseline cases, using PFC with a droop curve results in the frequency decline being arrested at a minimum (nadir) frequency f_{nadir} that is closer to the nominal $f_{\text{nom}} = 60$ Hz frequency level; further, the steady-state frequency f_{ss} after the PFC response is also closer to f_{nom} . It is important to prevent the difference $f_{\text{nom}} - f_{\text{nadir}}$ from exceeding a threshold that can

Active Power Control of Wind Power Plants for Grid Integration, Fig. 1 Simulation results showing the capability of wind power plants to provide APC services on a small-scale grid model. The total grid size is 3 GW, and a frequency event is induced due to the sudden active power imbalance when 5% of generation is taken offline at time = 200 s. Each wind power plant is derated to 90% of its rated capacity. The system response with all conventional generation (no wind) is compared to the cases when there are wind power plants on the grid at 10% penetration (i) with a baseline control system (wind baseline) where wind does not provide APC services and (ii) with an APC system (wind APC) that uses a 3% droop curve where either 50% or 100% of the wind power plants provide PFC

lead to underfrequency load shedding (UFLS) or rolling blackouts. The particular threshold varies across utility grids, but the largest such threshold in North America is 1.0 Hz.

Stability issues arising from the altered control algorithms must be analyzed (Buckspan et al. 2013; Wilches-Bernal et al. 2016). The trade-offs between aggressive primary frequency control and resulting structural loads also need to be evaluated carefully. Initial research shows that potential grid support can be achieved while not causing increases in average structural loading (Fleming et al. 2016). Further research is needed to more carefully assess how changes in structural loading affect fatigue damage and operations and maintenance costs.

Wind Turbine Automatic Generation Control

Secondary frequency control, also known as automatic generation control (AGC), occurs on a slower time scale than PFC. AGC commands can be generated from highly damped proportional integral (PI) controllers or logic controllers to regulate grid frequency and are used to control the power output of participating power plants. In many geographical regions, frequency regulation services are compensated through a competitive market, where power plants that provide faster and more accurate AGC command tracking are preferred.

An active power control system that combines both primary and secondary/AGC frequency control capabilities has been detailed in Aho et al. (2013a). Figure 2 presents experimental field test results of this active power controller, in response to prerecorded frequency events, showing how responsive wind turbines can be to both manual derating commands and rapidly changing automatic primary frequency control commands generated via a droop curve. Overall, results indicate that wind turbines can respond more rapidly than conventional power plants. However, increasing the power control and regulation performance of a wind turbine should be carefully considered due to a number of complicating factors, including coupling with existing control loops, a desire to

limit actuator usage and structural loading, and wind variability.

Active Power Control of Wind Power Plants

A wind power plant, often referred to as a wind farm, consists of many wind turbines. In wind power plants, wake effects can reduce generation in downstream turbines to less than 60% of the lead turbine (Barthelmie et al. 2009; Porté-Agel et al. 2013). There are many emerging areas of active research, including the modeling of wakes and wake effects and how these models can then be used to coordinate the control of individual turbines so that the overall wind power plant can reliably track the desired power reference command (Knudsen et al. 2015). A wind farm controller can be interconnected with the utility grid, transmission system operator (TSO), and individual turbines as shown in Fig. 3. By properly accounting for the wakes, wind farm controllers can allocate appropriate power reference commands to the individual wind turbines. Individual turbine generator torque and blade pitch controllers, as discussed earlier, can be designed so that each turbine follows the power reference command issued by the wind farm controller. Methods for intelligent, distributed control of entire wind farms to rapidly respond to grid frequency disturbances can significantly reduce frequency deviations and improve recovery speed to such disturbances (Boersma et al. 2019; Shapiro et al. 2017). Note that distributing a wind farm power reference among the operating individual wind turbines, in general, does not have a unique solution; further optimization can lead to structural load alleviation and thus prolongation of the operational lifespan of the individual wind turbines (Vali et al. 2019).

Summary and Future Directions

Ultimately, active power control of wind turbines and wind power plants should be combined with both demand-side management and storage to provide a more comprehensive solution that

The wind farm controller uses measurements of the utility grid frequency and automatic generation control power command signals from the grid operator to determine a power reference for each turbine in the wind farm

enables balancing electrical generation and electrical load with large penetrations of wind energy on the grid. Demand-side management (Callaway and Hiskens 2011; Palensky and Dietrich 2011) aims to alter the demand in order to mitigate peak electrical loads and hence to maintain sufficient control authority among generating units. As more effective and economical energy storage solutions (Pickard and Abbott 2012; Castillo and Gayme 2014) at the power plant scale are developed, wind (and solar) energy can then be stored when wind (and solar) energy availability is not well matched with electrical demand. Advances in wind forecasting (Pinson 2013; Okumus and Dinler 2016) will also improve wind power forecasts to facilitate more accurate scheduling of larger amounts of wind power on the grid. Finally, considering active power control in conjunction with reactive power and voltage control of wind power plants is also important for the stability and synchronization of the electrical power grid (Jain et al. 2015; Karthikeya and Schutt 2014).

Adaptive Control of Linear Time-Invariant Systems

Petros A. Ioannou

University of Southern California, Los Angeles, CA, USA

Abstract

Adaptive control of linear time-invariant (LTI) systems deals with the control of LTI systems whose parameters are constant but otherwise completely unknown. In some cases, large norm bounds as to where the unknown parameters are located in the parameter space are also assumed to be known. In general, adaptive control deals with LTI plants which cannot be controlled with fixed gain controllers, i.e., nonadaptive control methods, and their parameters even though assumed constant for design and analysis purposes may change over time in an unpredictable manner. Most of the adaptive control approaches for LTI systems use the so-called certainty equivalence principle where a control law motivated from the known parameter case is combined with an adaptive law for estimating on line the unknown parameters. The control law could be associated with different control

objectives and the adaptive law with different parameter estimation techniques. These combinations give rise to a wide class of adaptive control schemes. The two popular control objectives that led to a wide range of adaptive control schemes include model reference adaptive control (MRAC) and adaptive pole placement control (APPC). In MRAC, the control objective is for the plant output to track the output of a reference model, designed to represent the desired properties of the plant, for any reference input signal. APPC is more general and is based on control laws whose objective is to set the poles of the closed loop at desired locations chosen based on performance requirements. Another class of adaptive controllers for LTI systems that involves ideas from MRAC and APPC is based on multiple models, search methods, and switching logic. In this class of schemes, the unknown parameter space is partitioned to smaller subsets. For each subset, a parameter estimator or a stabilizing controller is designed or a combination of the two. The problem then is to identify which subset in the parameter space the unknown plant model belongs to and/or which controller is a stabilizing one and meets the control objective. A switching logic is designed based on different considerations to identify the most appropriate plant model or controller from the list of candidate plant models and/or controllers. In this entry, we briefly describe the above approaches to adaptive control for LTI systems.

Model Reference Adaptive Control

In model reference control (MRC), the desired plant behavior is described by a reference model which is simply an LTI system with a transfer function $W_m(s)$ and is driven by a reference

input. The controller transfer function $C(s, \theta^*)$, where θ^* is a vector with the coefficients of $C(s)$, is then developed so that the closed-loop plant has a transfer function equal to $W_m(s)$. This transfer function matching guarantees that the plant will match the reference model response for any reference input signal. In this case the plant transfer function $G_p(s, \theta_p^*)$, where θ_p^* is a vector with all the coefficients of $G_p(s)$, together with the controller transfer function $C(s, \theta^*)$ should lead to a closed-loop transfer function from the reference input r to the plant output y_p that is equal to $W_m(s)$, i.e.,

$$\frac{y_p(s)}{r(s)} = W_m(s) = \frac{y_m(s)}{r(s)}, \quad (1)$$

where y_m is the output of the reference model. For this transfer matching to be possible, $G_p(s)$ and $W_m(s)$ have to satisfy certain assumptions. These assumptions enable the calculation of the controller parameter vector θ^* as

$$\theta^* = F(\theta_p^*), \quad (2)$$

where F is a function of the plant parameters θ_p^* , to satisfy the matching equation (1). The function in (2) has a special form in the case of MRC that allows the design of both direct and indirect MRAC. For more general classes of controller structures, this is not possible in general as the function F is nonlinear. This transfer function matching guarantees that the tracking error $e_1 = y_p - y_m$ converges to zero for any given reference input signal r . If the plant parameter vector θ_p^* is known, then the controller parameters θ^* can be calculated using (2), and

the controller $C(s, \theta^*)$ can be implemented. We are considering the case where θ_p^* is unknown. In this case, the use of the certainty equivalence (CE) approach, (Astrom and Wittenmark 1995; Egardt 1979; Ioannou and Fidan 2006; Ioannou and Kokotovic 1983; Ioannou and Sun 1996; Landau et al. 1998; Morse 1996; Landau 1979; Narendra and Annaswamy 1989; Narendra and Balakrishnan 1997; Sastry and Bodson 1989; Stefanovic and Safonov 2011; Tao 2003) where the unknown parameters are replaced with their estimates, leads to the adaptive control scheme referred to as *indirect MRAC*, shown in Fig. 1a.

The unknown plant parameter vector θ_p^* is estimated at each time t denoted by $\theta_p(t)$, using an online parameter estimator referred to as adaptive law. The plant parameter estimate $\theta_p(t)$ at each time t is then used to calculate the controller parameter vector $\theta(t) = F(\theta_p(t))$ used in the controller $C(s, \theta)$. This class of MRAC is called indirect MRAC, because the controller parameters are not updated directly, but calculated at each time t using the estimated plant parameters. Another way of designing MRAC schemes is to parameterize the plant transfer function in terms of the desired controller parameter vector θ^* . This is possible in the MRC case, because the structure of the MRC law is such that we can use (2) to write

$$\theta_p^* = F^{-1}(\theta^*), \quad (3)$$

where F^{-1} is the inverse of the mapping $F(\cdot)$, and then express $G_p(s, \theta_p^*) = G_p(s, F^{-1}(\theta^*)) = \bar{G}_p(s, \theta^*)$. The adaptive law for estimating θ^* online can now be developed by using

Adaptive Control of Linear Time-Invariant Systems, Fig. 1 Structure of (a) indirect MRAC, (b) direct MRAC

$y_p = \bar{G}_p(s, \theta^*)u_p$ to obtain a parametric model that is appropriate for estimating the controller vector θ^* as the unknown parameter vector. The MRAC can then be developed using the CE approach as shown in Fig. 1b. In this case, the controller parameter $\theta(t)$ is updated directly without any intermediate calculations, and for this reason, the scheme is called *direct MRAC*.

The division of MRAC to indirect and direct is, in general, unique to MRC structures, and it is possible due to the fact that the inverse maps in (2) and (3) exist which is a direct consequence of the control objective and the assumptions the plant and reference model are required to satisfy for the control law to exist. These assumptions are summarized below:

Plant Assumptions: $G_p(s)$ is minimum phase, i.e., has stable zeros, its relative degree, $n^* = \text{number of poles} - \text{number of zeros}$, is known and an upper bound n on its order is also known. In addition, the sign of its high-frequency gain is known even though it can be relaxed with additional complexity.

Reference Model Assumptions: $W_m(s)$ has stable poles and zeros, its relative degree is equal to n^* that of the plant, and its order is equal or less to the one assumed for the plant, i.e., of n .

The above assumptions are also used to meet the control objective in the case of known parameters, and therefore the minimum phase and relative degree assumptions are characteristics of the control objective and do not arise because of adaptive control considerations. The relative degree matching is used to avoid the need to differentiate signals in the control law. The minimum phase assumption comes from the fact that the only way for the control law to force the closed-loop plant transfer function to be equal to that of the reference model is to cancel the zeros of the plant using feedback and replace them with those of the reference model using a feedforward term. Such zero pole cancelations are possible if the zeros are stable, i.e., the plant is minimum phase; otherwise stability cannot be guaranteed for nonzero initial conditions and/or inexact cancelations.

The design of MRAC in Fig. 1 has additional variations depending on how the adaptive law is designed. If the reference model is chosen to be strictly positive real (SPR) which limits its transfer function and that of the plant to have relative degree 1, the derivation of adaptive law and stability analysis is fairly straightforward, and for this reason, this class of MRAC schemes attracted a lot of interest. As the relative degree changes to 2, the design becomes more complex as in order to use the SPR property, the CE control law has to be modified by adding an extra nonlinear term. The stability analysis remains to be simple as a single Lyapunov function can be used to establish stability. As the relative degree increases further, the design complexity increases by requiring the addition of more nonlinear terms in the CE control law (Ioannou and Fidan 2006; Ioannou and Sun 1996). The simplicity of using a single Lyapunov function analysis for stability remains however. This approach covers both direct and indirect MRAC and lead to adaptive laws which contain no normalization signals (Ioannou and Fidan 2006; Ioannou and Sun 1996). A more straightforward design approach is based on the CE principle which separates the control design from the parameter estimation part and leads to a much wider class of MRAC which can be direct or indirect. In this case, the adaptive laws need to be normalized for stability, and the analysis is far more complicated than the approach based on SPR with no normalization. An example of such a direct MRAC scheme for the case of known sign of the high-frequency gain which is assumed to be positive for both plant and reference model is listed below:

Control law:

$$u_p = \theta_1^T(t) \frac{\alpha(s)}{\Lambda(s)} u_p + \theta_2^T \frac{\alpha(s)}{\Lambda(s)} y_p + \theta_3(t) y_p + c_0(t) r = \theta^T(t) \omega, \quad (4)$$

where $\alpha \triangleq \alpha_{n-2}(s) = [s^{n-2}, s^{n-3}, \dots, s, 1]^T$ for $n \geq 2$, and $\alpha(s) \triangleq 0$ for $n = 1$, and $\Lambda(s)$ is a monic polynomial with stable roots and degree $n - 1$ having numerator of $W_m(s)$ as a factor.

Adaptive law:

$$\dot{\theta} = \Gamma \varepsilon \phi, \quad (5)$$

where Γ is a positive definite matrix referred to as the adaptive gain and $\dot{\rho} = \gamma \varepsilon \xi$, $\varepsilon = \frac{e_1 - \rho \xi}{m_s^2}$, $m_s^2 = 1 + \phi^T \phi + u_f^2$, $\xi = \theta^T \phi + u_f$, $\phi = -W_m(s)\omega$, and $u_f = W_m(s)u_p$.

The stability properties of the above direct MRAC scheme which are typical for all classes of MRAC are the following (Ioannou and Fidan 2006; Ioannou and Sun 1996): (i) All signals in the closed-loop plant are bounded, and the tracking error e_1 converges to zero asymptotically and (ii) if the plant transfer function contains no zero pole cancelations and r is sufficiently rich of order $2n$, i.e., it contains at least n distinct frequencies, then the parameter error $|\tilde{\theta}| = |\theta - \theta^*|$ and the tracking error e_1 converge to zero exponentially fast.

Adaptive Pole Placement Control

Let us consider the SISO LTI plant:

$$y_p = G_p(s)u_p, \quad G_p(s) = \frac{Z_p(s)}{R_p(s)}, \quad (6)$$

where $G_p(s)$ is proper and $R_p(s)$ is a monic polynomial. The control objective is to choose the plant input u_p so that the closed-loop poles are assigned to those of a given monic Hurwitz polynomial $A^*(s)$, and y_p is required to follow a certain class of reference signals y_m assumed to satisfy $Q_m(s)y_m = 0$ where $Q_m(s)$ is known as the internal model of y_m and is designed to have all roots in $\text{Re}\{s\} \leq 0$ with no repeated roots on the $j\omega$ -axis. The polynomial $A^*(s)$, referred to as the desired closed-loop characteristic polynomial, is chosen based on the closed-loop performance requirements. To meet the control objective, we make the following assumptions about the plant:

P1. $G_p(s)$ is strictly proper with known degree, and $R_p(s)$ is a monic polynomial whose degree n is known and $Q_m(s)Z_p(s)$ and $R_p(s)$ are coprime.

Assumption P1 allows Z_p and R_p to be non-Hurwitz in contrast to the MRAC case where Z_p is required to be Hurwitz.

The design of the APPC scheme is based on the CE principle. The plant parameters are estimated at each time t and used to calculate the controller parameters that meet the control objective for the estimated plant as follows: Using (6) the plant equation can be expressed in a form convenient for parameter estimation via the model (Goodwin and Sin 1984; Ioannou and Fidan 2006; Ioannou and Sun 1996):

$$z = \theta_p^* \phi,$$

where $z = \frac{s^n}{\Lambda_p(s)} y_p$, $\theta_p^* = [\theta_b^{*T}, \theta_a^{*T}]^T$, $\phi = [\frac{\alpha_{n-1}^T(s)}{\Lambda_p(s)} u_p, -\frac{\alpha_{n-1}^T(s)}{\Lambda_p(s)} y_p]^T$, $\alpha_{n-1} = [s^{n-1}, \dots, s, 1]^T$, $\theta_a^* = [a_{n-1}, \dots, a_0]^T$, $\theta_b^* = [b_{n-1}, \dots, b_0]^T$, and $\Lambda_p(s)$ is a Hurwitz monic design polynomial. As an example of a parameter estimation algorithm, we consider the gradient algorithm

$$\dot{\theta}_p = \Gamma \varepsilon \phi, \quad \varepsilon = \frac{z - \theta_p^T \phi}{m_s^2}, \quad m_s^2 = 1 + \phi^T \phi, \quad (7)$$

where $\Gamma = \Gamma^T > 0$ is the adaptive gain and $\theta_p = [\hat{b}_{n-1}, \dots, \hat{b}_0, \hat{a}_{n-1}, \dots, \hat{a}_0]^T$ are the estimated plant parameters which can be used to form the estimated plant polynomials $\hat{R}_p(s, t) = s^n + \hat{a}_{n-1}(t)s^{n-1} + \dots + \hat{a}_1(t)s + \hat{a}_0(t)$ and $\hat{Z}_p(s, t) = \hat{b}_{n-1}(t)s^{n-1} + \dots + \hat{b}_1(t)s + \hat{b}_0(t)$ of $R_p(s)$ and $Z_p(s)$, respectively, at each time t . The adaptive control law is given as

$$u_p = \left(\Lambda(s) - \hat{L}(s, t) Q_m(s) \right) \frac{1}{\Lambda(s)} u_p - \hat{P}(s, t) \frac{1}{\Lambda(s)} (y_p - y_m), \quad (8)$$

where $\hat{L}(s, t)$ and $\hat{P}(s, t)$ are obtained by solving the polynomial equation $\hat{L}(s, t) \cdot Q_m(s) \cdot \hat{R}_p(s, t) + \hat{P}(s, t) \cdot \hat{Z}_p(s, t) = A^*(s)$ at each time t . The operation $X(s, t) \cdot Y(s, t)$ denotes a multiplication of polynomials where s is simply treated as a variable. The existence and

uniqueness of $\hat{L}(s, t)$ and $\hat{P}(s, t)$ is guaranteed provided $\hat{R}_p(s, t) \cdot Q_m(s)$ and $\hat{Z}_p(s, t)$ are coprime at each frozen time t . The adaptive laws that generate the coefficients of $\hat{R}_p(s, t)$ and $\hat{Z}_p(s, t)$ cannot guarantee this property, which means that at certain points in time, the solution $\hat{L}(s, t)$, $\hat{P}(s, t)$ may not exist. This problem is known as the stabilizability problem in indirect APPC and further modifications are needed in order to handle it (Goodwin and Sin 1984; Ioannou and Fidan 2006; Ioannou and Sun 1996). Assuming that the stabilizability condition holds at each time t , it can be shown (Goodwin and Sin 1984; Ioannou and Fidan 2006; Ioannou and Sun 1996) that all signals are bounded and the tracking error converges to zero with time. Other indirect adaptive pole placement control schemes include adaptive linear quadratic (Ioannou and Fidan 2006; Ioannou and Sun 1996). In principle any nonadaptive control scheme can be made adaptive by replacing the unknown parameters with their estimates in the calculation of the controller parameters. The design of direct APPC schemes is not possible in general as the map between the plant and controller parameters is nonlinear, and the plant parameters cannot be expressed as a convenient function of the controller parameters. This prevents parametrization of the plant transfer function with respect to the controller parameters as done in the case of MRC. In special cases where such parametrization is possible such as in MRAC which can be viewed as a special case of APPC, the design of direct APPC is possible. Chapters on ► [Adaptive Control: Overview](#), ► [Robust Adaptive Control](#), and ► [History of Adaptive Control](#) provide additional information regarding MRAC and APPC.

the adaptive law cannot guarantee such a property, an approach emerged that involves the precalculation of a set of controllers based on the partitioning of the plant parameter space. The problem then becomes one of identifying which one of the controllers is the most appropriate one. The switching to the “best” possible controller could be based on some logic that is driven by some cost index, multiple estimation models, and other techniques (Fekri et al. 2007; Hespanha et al. 2003; Kuipers and Ioannou 2010; Morse 1996; Narendra and Balakrishnan 1997; Stefanovic and Safonov 2011). One of the drawbacks of this approach is that it is difficult if at all possible to find a finite set of stabilizing controllers that cover the whole unknown parameter space especially for high-order plants. If found its dimension may be so large that makes it impractical. Another drawback that is present in all adaptive schemes is that in the absence of persistently exciting signals which guarantee that the input/output data have sufficient information about the unknown plant parameters, there is no guarantee that the controller the scheme converged to is indeed a stabilizing one. In other words, if switching is disengaged or the adaptive law is switched off, there is no guarantee that a small disturbance will not drive the corresponding LTI scheme unstable. Nevertheless these techniques allow the incorporation of well-established robust control techniques in designing a priori the set of controller candidates. The problem is that if the plant parameters change in a way not accounted for a priori, no controller from the set may be stabilizing leading to an unstable system.

Robust Adaptive Control

Search Methods, Multiple Models, and Switching Schemes

One of the drawbacks of APPC is the stabilizability condition which requires the estimated plant at each time t to satisfy the detectability and stabilizability condition that is necessary for the controller parameters to exist. Since

The MRAC and APPC schemes presented above are designed for LTI systems. Due to the adaptive law, the closed-loop system is no longer LTI but nonlinear and time varying. It has been shown using simple examples that the pure integral action of the adaptive law could cause parameter drift in the presence of small disturbances and/or unmodeled dynamics (Ioannou and Fidan

2006; Ioannou and Kokotovic 1983; Ioannou and Sun 1996) which could then excite the unmodeled dynamics and lead to instability. Modifications to counteract these possible instabilities led to the field of robust adaptive control whose focus was to modify the adaptive law in order to guarantee robustness with respect to disturbances, unmodeled dynamics, time-varying parameters, classes of nonlinearities, etc., by using techniques such as normalizing signals, projection, fixed and switching sigma modification, etc.

Adaptive Control of PDEs

Henrik Anfinssen and Ole Morten Aamo
Department of Engineering Cybernetics, NTNU,
Trondheim, Norway

Abstract

The infinite-dimensional backstepping method has recently been used for adaptive control of partial differential equations (PDEs). We will in this article briefly explain the main ideas for the three most commonly used methods for backstepping-based adaptive control of PDEs: Lyapunov-based design, identifier-based design, and swapping-based design. Swapping-based design is also demonstrated on a simple, scalar hyperbolic PDE with an uncertain in-domain parameter, clearly showing all the steps involved in using this method.

Keywords

Partial differential equations · Hyperbolic systems · Stabilization · Adaptive control · Parameter estimation · Infinite-dimensional backstepping

Introduction

The backstepping method has for the last decade and a half been used with great success for controller and observer design of partial differential equations (PDEs). Starting with nonadaptive results for parabolic PDEs (Liu

2003; Smyshlyaev and Krstić 2004, 2005; Krstić and Smyshlyaev 2008c), the method was extended to hyperbolic PDEs in Krstić and Smyshlyaev (2008b), where a controller for a scalar 1-D system was designed. Extensions to coupled hyperbolic PDEs followed in Vazquez et al. (2011), Di Meglio et al. (2013), and Hu et al. (2016). The backstepping approach offers a systematic way of designing controllers and observers for linear PDEs. One of its key strengths is that state feedback control laws and state observers can be derived for the infinite-dimensional system directly, with all analysis carried out in the infinite-dimensional framework, avoiding any artifacts caused by spatial discretization.

Backstepping has turned out to be well suited for dealing with uncertain systems by adaptive designs. The first result appeared in Smyshlyaev and Krstić (2006) where a parabolic PDE with an uncertain parameter is stabilized by backstepping. Extensions in several directions subsequently followed (Krstić and Smyshlyaev 2008a; Smyshlyaev and Krstić 2007a, b), culminating in the book *Adaptive Control of Parabolic PDEs* (Smyshlyaev and Krstić 2010). Most of the ideas developed for parabolic PDEs carry over to the hyperbolic case, with the first result appearing in Bernard and Krstić (2014) for a scalar equation. Extensions to coupled PDEs followed in Anfinssen and Aamo (2017a, b, c) and Yu et al. (2017), to mention a few.

Methods for Adaptive Control of PDEs

In Smyshlyaev and Krstić (2010) and Anfinssen and Aamo (2019), three main types of control design methods for adaptive control of PDEs are mentioned. These are

1. *Lyapunov-based design*: This approach directly addresses the problem of closed-loop stability, with the controller and adaptive law designed simultaneously from Lyapunov functions. It has been used for adaptive control design for parabolic PDEs in Krstić and Smyshlyaev (2008a) and for a scalar

hyperbolic PDE in Xu and Liu (2016). The Lyapunov method produces the simplest adaptive law in the sense of the controller's dynamical order, but the stability proof quickly becomes complicated as the systems get more complex. For this reason, no results extending those of Xu and Liu (2016) to coupled PDEs have appeared in the literature.

2. *Identifier-based design*: An identifier is usually a copy of the system dynamics with uncertain system parameters replaced by estimates and with error signals in terms of differences between measured and computed signals injected. Adaptive laws are chosen so that boundedness of the identifier error is ensured, before a control law is designed with the aim of stabilizing the identifier. Boundedness of the original system follows from boundedness of the identifier and the identifier error. Identifier-based designs have been developed for parabolic PDEs in Smyshlyaev and Krstić (2007a) and hyperbolic PDEs in Anfinssen and Aamo (2016a) and Anfinssen and Aamo (2018). The control law is designed independently of the adaptive laws, and hence the identifier-based method is based on certainty equivalence (CE). Since the method employs a copy of the system dynamics along with the adaptive laws, the dynamical order of the controller is larger than the dynamical order of the system.
3. *Swapping-based design*: In swapping-based designs, filters are carefully constructed so that the system states can be statically expressed in terms of the filter states, the unknown parameters and some error terms that are proved to converge to zero. The key property of the static parameterization is that the uncertain parameters appear linearly, so that well-established parameter identification laws such as the gradient law or the least squares method can be used to generate estimates. It also allows for normalization, so that the update laws remain bounded regardless of the boundedness of the system states. Adaptive estimates of the states can then be generated from the filters and parameter estimates by substituting the uncertain

parameters in the static parameterization with their respective estimates. A controller is designed for stabilization of the adaptive state estimates, meaning that this method, like the identifier-based method, is based on the certainty equivalence principle. The number of filters required when using this method typically equals the number of unknown parameters plus one, rendering the swapping-based adaptive controller of higher dynamical order than Lyapunov-based or identifier-based designs. Nevertheless, swapping-based design is the one most prominently used for adaptive control of hyperbolic PDEs since it extends to more complex systems in a natural way, as illustrated by the series of papers (Bernard and Krstić 2014; Anfinson and Aamo 2016b, 2017a, d).

Application of the Swapping Design Method

To give the reader a flavor of what adaptive control designs for PDEs involve, we will demonstrate swapping-based design for stabilization of a simple linear hyperbolic PDE. First, we introduce some notation. We will by $\|z\|$ and $\|z\|_\infty$ denote the L_2 -norm and ∞ -norm respectively, that is $\|z\| = \sqrt{\int_0^1 z^2(x)dx}$ and $\|z\|_\infty = \sup_{x \in [0,1]} |z(x)|$ for some function $z(x)$ defined for $x \in [0, 1]$. For a time-varying, real signal $f(t)$, the following vector spaces are used: $f \in \mathcal{L}_p \Leftrightarrow (\int_0^\infty |f(t)|^p dt)^{\frac{1}{p}} < \infty$ for $1 \leq p < \infty$, and $f \in \mathcal{L}_\infty \Leftrightarrow \sup_{t \geq 0} |f(t)| < \infty$. For two functions $u(x), v(x)$ on $x \in [0, 1]$, we define the operator $\equiv$ as $u \equiv v \Leftrightarrow \|u - v\|_\infty = 0$, $u \equiv 0 \Leftrightarrow \|u\|_\infty = 0$. Lastly, the following space is defined $\mathcal{B}([0, 1]) = \{u(x) \mid \|u\|_\infty < \infty\}$.

Consider the linear hyperbolic PDE

$$u_t(x, t) - u_x(x, t) = \theta u(0, t), \quad (1a)$$

$$u(1, t) = U(t), \quad (1b)$$

$$u(x, 0) = u_0(x) \quad (1c)$$

where $\theta \in \mathbb{R}$ is an uncertain parameter, while $u_0 \in \mathcal{B}([0, 1])$. Although θ is uncertain, we assume that we have some a priori bound, as formally stated in the following assumption:

Assumption 1 *A bound on θ is known. That is, we are in knowledge of a nonnegative constant $\bar{\theta}$ so that $|\theta| \leq \bar{\theta}$.*

Nonadaptive Control

A finite-time convergent stabilizing nonadaptive controller is Krstić and Smyshlyaev (2008b)

$$U(t) = -\theta \int_0^1 e^{\theta(1-\xi)} u(\xi, t) d\xi. \quad (2)$$

This can be proved using the *backstepping transformation*

$$w(x, t) = T[k, u(t)](x)$$

$$= u(x, t) - \int_0^x k(x - \xi) u(\xi, t) d\xi \quad (3)$$

with inverse

$$\begin{aligned} u(x, t) &= T^{-1}[\theta, w(t)](x) \\ &= w(x, t) - \theta \int_0^x w(\xi, t) d\xi \end{aligned} \quad (4)$$

where

$$k(x) = -\theta e^{\theta x} \quad (5)$$

is the *kernel function*. T maps system (1a) into the *target system*

$$w_t(x, t) - w_x(x, t) = 0, \quad w(x, 0) = w_0(x) \quad (6a)$$

$$w(1, t) = U(t)$$

$$+ \theta \int_0^1 e^{\theta(1-\xi)} u(\xi, t) d\xi. \quad (6b)$$

Choosing the control law $U(t)$ as (2) yields $w(1, t) = 0$, for which it trivially follows that $w \equiv 0$ for $t \geq 1$. From (4), it is clear that $w \equiv 0$ implies $u \equiv 0$.

Adaptive Control

Filter Design and Nonadaptive State Estimate

We introduce the input filter ψ and parameter filter ϕ as

$$\begin{aligned} \psi_t(x, t) - \psi_x(x, t) &= 0, \\ \psi(1, t) &= U(t), \\ \psi(x, 0) &= \psi_0(x) \\ \phi_t(x, t) - \phi_x(x, t) &= 0, \\ \phi(1, t) &= u(0, t), \\ \phi(x, 0) &= \phi_0(x). \end{aligned} \quad (7a) \quad (7b)$$

Using the filters, a *nonadaptive estimate* $\bar{u}$ of the system state u can be generated as

$$\begin{aligned} \bar{u}(x, t) &= \psi(x, t) + \theta F[\phi(t)](x), \\ F[\phi(t)](x) &= \int_x^1 \phi(1 - \xi + x, t) d\xi. \end{aligned} \quad (8)$$

Notice that $\bar{u}$ is linear in the uncertain parameter θ and that F , ϕ , and ψ are known.

Lemma 1 Consider system (1a), filters (7), and the variable $\bar{u}$ generated from (8). For $t \geq 1$, we have $\bar{u} \equiv u$.

Proof. Defining, $e(x, t) = u(x, t) - \bar{u}(x, t) = u(x, t) - \psi(x, t) - \theta F[\phi(t)](x)$, it is straightforward to show, using the dynamics (1a) and (7), that e satisfies the dynamics

$$\begin{aligned} e_t(x, t) - e_x(x, t) &= 0, \\ e(1, t) &= 0, e(x, 0) = e_0(x) \end{aligned} \quad (9)$$

and hence $e \equiv 0$ and $\bar{u} \equiv u$ for $t \geq 1$. $\square$

Adaptive Law

From the linear relationship $u(x, t) = \bar{u}(x, t) = \psi(x, t) + \theta F[\phi(t)](x)$ for $t \geq 1$ ensured by Lemma 1, we have $u(0, t) = \psi(0, t) + \theta F[\phi(t)](0)$ from which we propose the gradient adaptive law with normalization

$$\dot{\hat{\theta}}(t) = \begin{cases} \text{proj}_{\bar{\theta}} \left\{ \gamma \frac{\hat{e}(0, t) \int_0^1 \phi(x, t) dx}{1 + \|\phi(t)\|^2}, \hat{\theta}(t) \right\}, & \text{for } t \geq 1 \\ 0 & \text{otherwise} \end{cases} \quad \hat{\theta}(0) = \hat{\theta}_0, \quad |\hat{\theta}_0| \leq \bar{\theta} \quad (10)$$

for some gain $\gamma > 0$, $\hat{\theta}_0$ chosen inside the feasible domain as given by Assumption 1 and where

$$\hat{e}(x, t) = u(x, t) - \hat{u}(x, t), \quad \hat{u}(x, t) = \psi(x, t) + \hat{\theta}(t) F[\phi(t)](x), \quad (11)$$

and the projection operator is defined as

$$\text{proj}_a(\tau, \omega) = \begin{cases} 0 & \text{if } (\omega = -a \text{ and } \tau \leq 0) \text{ or } (\omega = a \text{ and } \tau \geq 0) \\ \tau & \text{otherwise.} \end{cases} \quad (12)$$

Notice that the *adaptive state estimate* $\hat{u}$ is obtained from the nonadaptive estimate by simply substituting the uncertain parameter θ with its adaptive estimate provided by (10). The following lemma states important properties regarding the adaptive law which are crucial in the closed-loop stability analysis.

Lemma 2 *Subject to Assumption 1, the adaptive law (10) with initial condition $|\hat{\theta}_0| \leq \bar{\theta}$ provides the following signal properties*

$$|\hat{\theta}(t)| \leq \bar{\theta}, \forall t \geq 0 \quad (13a)$$

$$\dot{\hat{\theta}}, \sigma \in \mathcal{L}_2 \cap \mathcal{L}_\infty, \quad \sigma(t) = \frac{\hat{e}(0, t)}{\sqrt{1 + \|\phi(t)\|^2}}. \quad (13b)$$

Proof. Property (13a) follows from the initial condition (10) and the projection operator (Anfinssen and Aamo 2019, Lemma A.1). Consider

$$V(t) = \frac{1}{2\gamma} \tilde{\theta}^2(t), \quad \tilde{\theta}(t) = \theta - \hat{\theta}(t). \quad (14)$$

For $t \in [0, 1)$, we will trivially have $\dot{V}(t) = 0$. For $t \geq 1$, we have, using the property $-\tilde{\theta} \text{proj}_{\bar{\theta}}(\tau, \hat{\theta}) \leq -\tilde{\theta}\tau$ (Anfinssen and Aamo 2019, Lemma A.1), that

$$\dot{V}(t) \leq -\tilde{\theta}(t) \frac{\hat{e}(0, t) \int_0^1 \phi(x, t) dx}{1 + \|\phi(t)\|^2}. \quad (15)$$

From (8), (11) and Lemma 1, we have, for $t \geq 1$ $\hat{e}(0, t) = u(0, t) - \hat{u}(0, t) = \psi(0, t) + \theta F[\phi(t)](0) - \psi(0, t) - \hat{\theta}(t) F[\phi(t)](0) = \tilde{\theta}(t) \int_0^1 \phi(x, t) dx$, and substituting this into (15), we obtain

$$\dot{V}(t) \leq -\sigma^2(t), \quad (16)$$

where we have used the definition of σ stated in (13b). This proves that V is bounded and nonincreasing and hence has a limit, V_∞ , as $t \rightarrow \infty$. Integrating (16) in time from zero to infinity gives

$$\begin{aligned} \int_0^\infty \sigma^2(t) dt &\leq - \int_0^\infty \dot{V}(t) dt \\ &= V(0) - V_\infty \leq V(0) \leq \frac{2}{\gamma} \bar{\theta}^2 < \infty, \end{aligned} \quad (17)$$

and hence $\sigma \in \mathcal{L}_2$. Moreover, using $\hat{e}(0, t) = \tilde{\theta}(t) \int_0^1 \phi(x, t) dx$, we have

$$\begin{aligned} \sigma^2(t) &= \frac{\hat{e}^2(0, t)}{1 + \|\phi(t)\|^2} \\ &\leq \tilde{\theta}^2(t) \frac{(\int_0^1 \phi(x, t) dx)^2}{1 + \|\phi(t)\|^2} \\ &\leq \tilde{\theta}^2(t) \frac{\int_0^1 \phi^2(x, t) dx}{1 + \|\phi(t)\|^2} \\ &\leq \tilde{\theta}^2(t) \frac{\|\phi(t)\|^2}{1 + \|\phi(t)\|^2} \leq \tilde{\theta}^2(t) \leq 4\bar{\theta}^2 < \infty \end{aligned} \quad (18)$$

where we used Cauchy-Schwarz' inequality and hence $\sigma \in \mathcal{L}_\infty$. For $t \in [0, 1)$ or if the projection is active, the adaptive law (10) is zero, and hence boundedness of $\dot{\hat{\theta}}$ follows. For $t \geq 1$, we have for an inactive projection and inserting $\hat{e}(0, t) = \tilde{\theta}(t) \int_0^1 \phi(x, t) dx$, that

$$\begin{aligned} |\dot{\hat{\theta}}(t)| &= \gamma \left| \frac{\hat{e}(0, t) \int_0^1 \phi(x, t) dx}{1 + \|\phi(t)\|^2} \right| \\ &= \gamma \left| \frac{\hat{e}(0, t)}{\sqrt{1 + \|\phi(t)\|^2}} \frac{\int_0^1 \phi(x, t) dx}{\sqrt{1 + \|\phi(t)\|^2}} \right| \\ &\leq \gamma |\sigma(t)| \end{aligned} \quad (19)$$

and since $\sigma \in \mathcal{L}_2 \cap \mathcal{L}_\infty$, it follows that $\dot{\hat{\theta}} \in \mathcal{L}_2 \cap \mathcal{L}_\infty$. $\square$

Adaptive Control Law

As mentioned, the swapping-based design employs certainty equivalence. An adaptive stabilizing control law is hence obtained from the nonadaptive control law (2) by simply substituting the uncertain parameter θ by its

adaptive estimate $\hat{\theta}$ and the unmeasured state u by its adaptive state estimate $\hat{u}$ to obtain

$$U(t) = -\hat{\theta}(t) \int_0^1 e^{\hat{\theta}(t)(1-\xi)} \hat{u}(\xi, t) d\xi. \quad (20)$$

We obtain the following main result for the closed-loop dynamics.

Theorem 1 *Consider system (1a), filters (7), the adaptive law (10), and the adaptive state estimate (11). The control law (20) ensures*

$$\|u\|, \|\psi\|, \|\phi\|, \|u\|_\infty, \|\psi\|_\infty, \|\phi\|_\infty \in \mathcal{L}_2 \cap \mathcal{L}_\infty \quad (21a)$$

$$\|u\|, \|\psi\|, \|\phi\|, \|u\|_\infty, \|\psi\|_\infty, \|\phi\|_\infty \rightarrow 0. \quad (21b)$$

The proof of Theorem 1 involves several steps. First, a backstepping transformation with a time-varying kernel function brings the adaptive state estimate's dynamics into a target system which involves the parameter estimate as well as its time derivatives (adaptive laws). Next, a relatively comprehensive Lyapunov analysis involving heavy use of Cauchy-Schwarz' and Young's inequalities, along with the properties of Lemma 2, follows, which establishes that the Lyapunov function

$$V_1(t) = 4 \int_0^1 (1+x) \eta^2(x, t) dx + \int_0^1 (1+x) \phi^2(x, t) dx \quad (22)$$

satisfies

$$\dot{V}_1(t) \leq -cV_1(t) + l_1(t)V_1(t) + l_2(t) \quad (23)$$

where c is a positive constant, $\eta(x, t) = T[\hat{k}, \hat{u}(t)](x)$ with $\hat{k}$ given by (5) with θ replaced by $\hat{\theta}$ and l_1 and l_2 are non-negative and integrable (i.e., $l_1, l_2 \geq 0, l_1, l_2 \in \mathcal{L}_1$). Finally, established stability and convergence results from the literature on adaptive control are applied.

Summary and Future Directions

It is apparent from the example that the swapping-based method is quite involved even for the simple scalar system. However, the method extends to more complex systems in a natural way and can be modified (see Anfinson and Aamo 2019) to accommodate spatially varying parameters, any number of coupled hyperbolic equations carrying information in either direction, interface with ODE's at the boundary or in the interior, etc. The backstepping transformation induces a complicated relationship between the uncertain parameters of the system in its original coordinates and the uncertainties appearing in the target system, often leading to vast over-parameterization accompanied by poor robustness properties of the closed loop. Robustness in general is a topic for further investigation before the method is ripe for application to practical problems (Lamare et al. 2018). How to deal with nonlinearities is another important direction of future research. While backstepping was invented for systems described by nonlinear ordinary differential equations, it has had little success on the nonlinear arena for PDEs. Some local stability results exist for linear backstepping designs (applied to semi-linear PDEs without uncertainty, Coron et al. 2013), but it is unclear if backstepping can be helpful in providing truly nonlinear control laws in the PDE case. For semi-linear systems without uncertainty, nonlinear state feedback laws and state observers have been designed by an approach not using backstepping (Strecker and Aamo 2017). Interestingly, though, the state feedback law reduces to the backstepping control law in the linear case.

Introduction

What Is Adaptive Control

Feedback control has a long history of using sensing, decision, and actuation elements to achieve an overall goal. The general structure of a control system may be illustrated in Fig. 1. It has long been known that high fidelity control relies on knowledge of the system to be controlled. For example, in most cases, knowledge of the plant gain and/or time constants (represented by θ_p in Fig. 1) is important in feedback control design. In addition, disturbance characteristics (e.g., frequency of a sinusoidal disturbance), θ_d in Fig. 1, are important in feedback compensator design.

Many control design and synthesis techniques are model based, using prior knowledge of both model structure and parameters. In other cases, a fixed controller structure is used, and the controller parameters, θ_c in Fig. 1, are tuned empirically during control system

Adaptive Control: Overview, Fig. 1 General control and adaptive control diagram

commissioning. However, if the plant parameters vary widely with time or have large uncertainties, these approaches may be inadequate for high-performance control.

There are two main ways of approaching high-performance control with unknown plant and disturbance characteristics:

1. Robust control ([► Optimization-Based Robust Control](#)), wherein a controller is designed to perform adequately despite the uncertainties. Variable structure control may have very high levels of robustness in some cases and therefore is a special class of robust nonlinear control.
2. Adaptive control, where the controller learns and adjusts its strategy based on measured data. This frequently takes the form where the controller parameters, θ_c , are time-varying functions that depend on the available data ($y(t)$, $u(t)$, and $r(t)$). Adaptive control has close links to intelligent control (including neural control ([► Optimal Control and the Dynamic Programming Principle](#)), where specific types of learning are considered) and also to stochastic adaptive control ([► Stochastic Adaptive Control](#)).

Robust control is most useful when there are large unmodeled dynamics (i.e., structural uncertainties), relatively high levels of noise, or rapid and unpredictable parameter changes. Conversely, for slow or largely predictable parameter variations, with relatively well-known model structure and limited noise levels, adaptive control may provide a very useful tool for high-performance control (Åström and Wittenmark 2008).

Varieties of Adaptive Control

One practical variant of adaptive control is controller auto-tuning (► [Autotuning](#)). Auto-tuning is particularly useful for PID and similar controllers and involves a specific phase of signal injection, followed by analysis, PID gain computation, and implementation. These techniques are an important aid to commissioning and maintenance of distributed control systems.

There are also large classes of adaptive controllers that are continuously monitoring the plant input-output signals to adjust the strategy. These adjustments are often parametrized by a relatively small number of coefficients, θ_C . These include schemes where the controller parameters are directly adjusted using measureable data (also referred to as “implicit,” since there is no explicit plant model generated). Early examples of this often included model reference adaptive control (► [Model Reference Adaptive Control](#)). Other schemes (Middleton et al. 1988) explicitly estimate a plant model θ_P ; thereafter, performing online control design and, therefore, the adaptation of controller parameters θ_C are indirect. This then led on to a range of other adaptive control techniques applicable to linear systems (► [Adaptive Control of Linear Time-Invariant Systems](#)).

There have been significant questions concerning the sensitivity of some adaptive control algorithms to unmodeled dynamics, time-varying systems, and noise (Ioannou and Kokotovic

1984; Rohrs et al. 1985). This prompted a very active period of research to analyze and redesign adaptive control to provide suitable robustness (► [Robust Adaptive Control](#)) (e.g., Anderson et al. 1986; Ioannou and Sun 2012) and parameter tracking for time-varying systems (e.g., Kresselmeier 1986; Middleton and Goodwin 1988).

Work in this area further spread to nonparametric methods, such as switching, or supervisory adaptive control (► [Switching Adaptive Control](#)) (e.g., Fu and Barmish 1986; Morse et al. 1992). In addition, there has been a great deal of work on the more difficult problem of adaptive control for nonlinear systems (► [Nonlinear Adaptive Control](#)).

A further adaptive control technique is extremum seeking control (► [Extremum Seeking Control](#)). In extremum seeking (or self optimizing) control, the desired reference for the system is unknown, instead we wish to maximize (or minimize) some variable in the system (Ariyur and Krstic 2003). These techniques have quite distinct modes of operation that have proven important in a range of applications.

A final control algorithm that has nonparametric features is iterative learning control (► [Iterative Learning Control](#)) (Amann et al. 1996; Moore 1993). This control scheme considers a system with a highly structured, namely, repetitive finite run, control problem. In this case, by taking a nonparametric approach of utilizing information from previous run(s), in many cases, near-perfect asymptotic tracking can be achieved.

Adaptive control has a rich history (► [History of Adaptive Control](#)) and has been established as an important tool for some classes of control problems.

Adaptive Cruise Control

Rajesh Rajamani

Department of Mechanical Engineering,
University of Minnesota, Twin Cities,
Minneapolis, MN, USA

Abstract

This chapter discusses advanced cruise control automotive technologies, including adaptive cruise control (ACC) in which spacing control, speed control, and a number of transitional maneuvers must be performed. The ACC system must satisfy difficult performance requirements of vehicle stability and string stability. The technical challenges involved and the control design techniques utilized in ACC system design are presented.

Keywords

Collision avoidance · String stability ·
Traffic stability · Vehicle following

Introduction

Adaptive cruise control (ACC) is an extension of cruise control. An ACC vehicle includes a radar, a lidar, or other sensor that measures the distance to any preceding vehicle in the same lane on the highway. In the absence of preceding vehicles, the speed of the car is controlled to a driver-desired value. In the presence of a preceding vehicle, the controller determines whether the vehicle should switch from speed control to spacing control. In spacing control, the distance to the preceding car is controlled to a desired value.

A different form of advanced cruise control is a *forward collision avoidance* (FCA) system. An FCA system uses a distance sensor to determine if the vehicle is approaching a car ahead too quickly and will automatically apply brakes to minimize the chances of a forward collision. For the 2013 model year, 29 % vehicles have

forward collision warning as an available option and 12 % include autonomous braking for a full FCA system. Examples of models in which an FCA system is standard are the Mercedes Benz G-class and the Volvo S-60, S-80, XC-60, and XC-70.

It should be noted that an FCA system does not involve steady-state vehicle following. An ACC system on the other hand involves control of speed and spacing to desired steady-state values.

ACC systems have been in the market in Japan since 1995, in Europe since 1998, and in the US since 2000. An ACC system provides enhanced driver comfort and convenience by allowing extended operation of the cruise control option even in the presence of other traffic.

Controller Architecture

The ACC system has two modes of steady state operation: speed control and vehicle following (i.e., spacing control). Speed control is traditional cruise control and is a well-established technology. A proportional-integral controller based on feedback of vehicle speed (calculated from rotational wheel speeds) is used in cruise control (Rajamani 2012).

Controller design for vehicle following is the primary topic of discussion in the sections titled “Vehicle Following Requirements” and “String Stability Analysis” in this chapter.

Transitional maneuvers and transitional control algorithms are discussed in the section titled “Transitional Maneuvers” in this chapter.

The longitudinal control system architecture for an ACC vehicle is typically designed to be hierarchical, with an upper-level controller and a lower-level controller, as shown in Fig. 1.

The upper-level controller determines the desired acceleration for the vehicle. The lower level controller determines the throttle and/or brake commands required to track the desired acceleration. Vehicle dynamic models, engine maps, and nonlinear control synthesis techniques are used in the design of the lower controller

Adaptive Cruise Control, Fig. 1 Structure of longitudinal control system

(Rajamani 2012). This chapter will focus only on the design of the upper controller, also known as the ACC controller.

As far as the upper-level controller is concerned, the plant model for control design is

$$\ddot{x}_i = u \quad (1)$$

where the subscript i denotes the i th car in a string of consecutive ACC cars. The acceleration of the car is thus assumed to be the control input. However, due to the finite bandwidth associated with the lower level controller, each car is actually expected to track its desired acceleration imperfectly. The objective of the upper level controller design is therefore stated as that of meeting required performance specifications robustly in the presence of a first order lag in the lower-level controller performance:

$$\ddot{x}_i = \frac{1}{\tau s + 1} \ddot{x}_{i,\text{des}} = \frac{1}{\tau s + 1} u_i. \quad (2)$$

Equation (1) is thus assumed to be the nominal plant model while the performance specifications have to be met even if the actual plant model were given by Eq. (2). The lag τ typically has a value between 0.2 and 0.5 s (Rajamani 2012).

Adaptive Cruise Control,

Fig. 2 String of adaptive cruise control vehicles

Vehicle Following Requirements

In the vehicle following mode of operation, the ACC vehicle maintains a desired spacing from the preceding vehicle. The two important performance specifications that the vehicle following control system must satisfy are: individual vehicle stability and string stability.

(a) Individual vehicle stability

Consider a string of vehicles on the highway using a longitudinal control system for vehicle following, as shown in Fig. 2. Let x_i be the location of the i th vehicle measured from an inertial reference. The spacing error for the i th vehicle (the ACC vehicle under consideration) is then defined as

$$\delta_i = x_i - x_{i-1} + L_{\text{des}}. \quad (3)$$

Here, L_{des} is the desired spacing and includes the preceding vehicle length ℓ_{i-1} . L_{des} could be chosen as a function of variables such as the vehicle speed $\dot{x}_i$. The ACC control law is said to provide individual vehicle stability if the spacing error of the ACC vehicle converges to zero when the preceding vehicle is operating at constant speed:

$$\ddot{x}_{i-1} \rightarrow 0 \Rightarrow \delta_i \rightarrow 0. \quad (4)$$

(b) String stability

The spacing error is expected to be non-zero during acceleration or deceleration of the preceding vehicle. It is important then to describe how the spacing error would propagate from vehicle

to vehicle in a string of ACC vehicles during acceleration. The string stability of a string of ACC vehicles refers to a property in which spacing errors are guaranteed not to amplify as they propagate towards the tail of the string (Swaroop and Hedrick 1996).

String Stability Analysis

In this section, mathematical conditions that ensure string stability are provided.

Let δ_i and δ_{i-1} be the spacing errors of consecutive ACC vehicles in a string. Let $\hat{H}(s)$ be the transfer function relating these errors:

$$\hat{H}(s) = \frac{\hat{\delta}_i}{\hat{\delta}_{i-1}}(s). \quad (5)$$

The following two conditions can be used to determine if the system is string stable:

(a) The transfer function $\hat{H}(s)$ should satisfy

$$\|\hat{H}(s)\|_{\infty} \leq 1. \quad (6)$$

(b) The impulse response function $h(t)$ corresponding to $\hat{H}(s)$ should not change sign (Swaroop and Hedrick 1996), i.e.,

$$h(t) > 0 \quad \forall t \geq 0. \quad (7)$$

The reasons for these two requirements to be satisfied are described in Rajamani (2012). Roughly speaking, Eq. (6) ensures that $\|\delta_i\|_2 \leq \|\delta_{i-1}\|_2$, which means that the energy in the spacing error signal decreases as the spacing error propagates towards the tail of the string. Equation (7) ensures that the steady state spacing

errors of the vehicles in the string have the same sign. This is important because a positive spacing error implies that a vehicle is closer than desired while a negative spacing error implies that it is further apart than desired. If the steady state value of δ_i is positive while that of δ_{i-1} is negative, then this might be dangerous due to the vehicle being closer, even though in terms of magnitude δ_i might be smaller than δ_{i-1} .

If conditions (6) and (7) are both satisfied, then $\|\delta_i\|_\infty \leq \|\delta_{i-1}\|_\infty$ (Rajamani 2012).

Constant Inter-vehicle Spacing

The ACC system only utilizes on board sensors like radar and does not depend on inter-vehicle communication from other vehicles. Hence the only variables available as feedback for the upper controller are inter-vehicle spacing, relative velocity and the ACC vehicle's own velocity.

Under the constant spacing policy, the spacing error of the i th vehicle was defined in Eq. (3).

If the acceleration of the vehicle can be instantaneously controlled, then it can be shown that a linear control system of the type

$$\ddot{x}_i = -k_p \delta_i - k_v \dot{\delta}_i \quad (8)$$

results in the following closed-loop transfer function between consecutive spacing errors

$$\hat{H}(s) = \frac{\hat{\delta}_i}{\hat{\delta}_{i-1}}(s) = \frac{k_p + k_v s}{s^2 + k_v s + k_p}. \quad (9)$$

Equation (9) describes the propagation of spacing errors along the vehicle string.

All positive values of k_p and k_v guarantee individual vehicle stability. However, it can be shown that there are no positive values of k_p and k_v for which the magnitude of $G(s)$ can be guaranteed to be less than unity at all frequencies. The details of this proof are available in Rajamani (2012).

Thus, the constant spacing policy will always be string unstable.

Constant Time-Gap Spacing

Since the constant spacing policy is unsuitable for autonomous control, a better spacing policy that can ensure both individual vehicle stability and string stability must be used. The constant time-gap (CTG) spacing policy is such a spacing policy. In the CTG spacing policy, the desired inter-vehicle spacing is not constant but varies with velocity. The spacing error is defined as

$$\delta_i = x_i - x_{i-1} + L_{\text{des}} + h\dot{x}_i. \quad (10)$$

The parameter h is referred to as the time-gap.

The following controller based on the CTG spacing policy can be used to regulate the spacing error at zero (Swaroop et al. 1994):

$$\ddot{x}_{i_des} = -\frac{1}{h}(\dot{x}_i - \dot{x}_{i-1} + \lambda\delta_i) \quad (11)$$

With this control law, it can be shown that the spacing errors of successive vehicles δ_i and δ_{i-1} are independent of each other:

$$\dot{\delta}_i = -\lambda\delta_i \quad (12)$$

Thus, δ_i is independent of δ_{i-1} and is expected to converge to zero as long as $\lambda > 0$. However, this result is only true if any desired acceleration can be instantaneously obtained by the vehicle i.e., if $\tau = 0$.

In the presence of the lower controller and actuator dynamics given by Eq. (2), it can be shown that the dynamic relation between δ_i and δ_{i-1} in the transfer function domain is

$$\hat{H}(s) = \frac{s + \lambda}{h\tau s^3 + hs^2 + (1 + \lambda h)s + \lambda} \quad (13)$$

The string stability of this system can be analyzed by checking if the magnitude of the above transfer function is always less than or equal to 1. It can be shown that this is the case at all frequencies if and only if (Rajamani 2012)

$$h \geq 2\tau. \quad (14)$$

Further, if Eq. (14) is satisfied, then it is also guaranteed that one can find a value of λ such that Eq. (7) is satisfied. Thus the condition (14) is necessary (Swaroop and Hedrick 1996) for string stability.

Since the typical value of τ is of the order of 0.5 s, Eq. (14) implies that ACC vehicles must maintain at least a 1-s time gap between vehicles for string stability.

Transitional Maneuvers

While under speed control, an ACC vehicle might suddenly encounter a new vehicle in its lane (either due to a lane change or due to a slower moving preceding vehicle). The ACC vehicle must then decide whether to continue to operate under the speed control mode or transition to the vehicle following mode or initiate hard braking. If a transition to vehicle following is required, a transitional trajectory that will bring the ACC vehicle to its steady state following distance needs to be designed. Similarly, a decision on the mode of operation and design of a transitional trajectory are required when an ACC vehicle loses its target.

The regular CTG control law cannot directly be used to follow a newly encountered vehicle, see Rajamani (2012) for illustrative examples.

When a new target vehicle is encountered by the ACC vehicle, a “range – range rate” diagram can be used (Fancher and Bareket 1994) to decide if

- The vehicle should use speed control.
- The vehicle should use spacing control (with a defined transition trajectory in which desired spacing varies slowly with time)
- The vehicle should brake as hard as possible in order to avoid a crash.

The maximum allowable values for acceleration and deceleration need to be taken into account in making these decisions.

For the range – range rate ($R - \dot{R}$) diagram, define range R and range rate $\dot{R}$ as

$$R = x_{i-1} - x_i \quad (15)$$

$$\dot{R} = \dot{x}_{i-1} - \dot{x}_i = V_{i-1} - V_i \quad (16)$$

where x_{i-1} , x_i , V_{i-1} , and V_i are inertial positions and velocities of the preceding vehicle and the ACC vehicle respectively.

A typical $R - \dot{R}$ diagram is shown in Fig. 3 (Fancher and Bareket 1994). Depending on the measured real-time values of R and $\dot{R}$, and the $R - \dot{R}$ diagram in Fig. 3, the ACC system determines the mode of longitudinal control. For instance, in region 1, the vehicle continues

Adaptive Cruise Control,

Fig. 3 Range vs. range-rate diagram

Adaptive Cruise Control, Fig. 4 Switching line for spacing control

to operate under speed control. In region 2, the vehicle operates under spacing control. In region 3, the vehicle decelerates at the maximum allowed deceleration so as to try and avoid a crash.

The switching line from speed to spacing control is given by

$$R = -T\dot{R} + R_{\text{final}} \quad (17)$$

where T is the slope of the switching line. When a slower vehicle is encountered at a distance larger than the desired final distance R_{final} , the switching line shown in Fig. 4 can be used to determine when and whether the vehicle should switch to spacing control. If the distance R is greater than that given by the line, speed control should be used.

The overall strategy (shown by trajectory ABC) is to first reduce gap at constant $\dot{R}$ and then follow the desired spacing given by the switching line of Eq. (17).

The control law during spacing control on this transitional trajectory is as follows. Depending on the value of $\dot{R}$, determine R from Eq. (17). Then use R as the desired inter-vehicle spacing in the PD control law

$$\ddot{x}_{\text{des}} = -k_p(x_i - R) - k_d(\dot{x}_i - \dot{R}) \quad (18)$$

The trajectory of the ACC vehicle during constant deceleration is a parabola on the $R - \dot{R}$ diagram (Rajamani 2012).

The switching line should be such that travel along the line is comfortable and does not constitute high deceleration. The deceleration during coasting (zero throttle and zero braking) can be used to determine the slope of the switching line (Rajamani 2012).

Note that string stability is not a concern during transitional maneuvers (Rajamani 2012).

Traffic Stability

In addition to individual vehicle stability and string stability, another type of stability analysis that has received significant interest in ACC literature is traffic flow stability. Traffic flow stability refers to the stable evolution of traffic velocity and traffic density on a highway section, for given inflow and outflow conditions. One well-known result in this regard in literature is that traffic flow is defined to be stable if $\frac{\partial q}{\partial \rho}$ is positive, i.e., as the density ρ of traffic increases, traffic flow rate q must increase (Swaroop and Rajagopal 1999). If this condition is not satisfied, the highway section would be unable to accommodate any constant inflow of vehicles from an oncoming ramp. The steady state traffic flow on the highway section would come to a stop, if the ramp inflow did not stop (Swaroop and Rajagopal 1999).

It has been shown that the constant time-gap spacing policy used in ACC systems has a negative $q - \rho$ slope and thus does not lead to traffic flow stability (Swaroop and Rajagopal 1999). It has also been shown that it is possible to design other spacing policies (in which the desired spacing between vehicles is a nonlinear function of speed, instead of being proportional to speed) that can provide stable traffic flow (Santhanakrishnan and Rajamani 2003).

The importance of traffic flow stability has not been fully understood by the research community. Traffic flow stability is likely to become important when the number of ACC vehicles

on the highway increase and their penetration percentage into vehicles on the road becomes significant.

Recent Automotive Market Developments

The latest versions of ACC systems on the market have been enhanced with collision warning, integrated brake support, and stop-and-go operation functionality.

The collision warning feature uses the same radar as the ACC system to detect moving vehicles ahead and determine whether driver intervention is required. In this case, visual and audio warnings are provided to alert the driver and brakes are pre-charged to allow quick deceleration. On Ford's ACC-equipped vehicles, brakes are also automatically applied when the driver lifts the foot off from the accelerator pedal in a detected collision warning scenario.

When enabled with stop-and-go functionality, the ACC system can also operate at low vehicle speeds in heavy traffic. The vehicle can be automatically brought to a complete stop when needed and restarted automatically. Stop-and-go is an expensive option and requires the use of multiple radar sensors on each car. For instance, the BMW ACC system uses two short range and one long range radar sensor for stop-and-go operation.

The 2013 versions of ACC on the Cadillac ATS and on the Mercedes Distronic systems are also being integrated with camera based lateral lane position measurement systems. On the Mercedes Distronic systems, a camera steering assist system provides automatic steering, while on the Cadillac ATS, a camera based system provides lane departure warnings.

Future Directions

Current ACC systems use only on-board sensors and do not use wireless communication with

other vehicles. There is a likelihood of evolution of current systems into co-operative adaptive cruise control (CACC) systems which utilize wireless communication with other vehicles and highway infrastructure. This evolution could be facilitated by the dedicated short-range communications (DSRC) capability being developed by government agencies in the US, Europe and Japan. In the US, DSRC is being developed with a primary goal of enabling communication between vehicles and with infrastructure to reduce collisions and support other safety applications. In CACC, wireless communication could provide acceleration signals from several preceding downstream vehicles. These signals could be used in better spacing policies and control algorithms to improve safety, ensure string stability, and improve traffic flow.

Adaptive Horizon Model Predictive Control and Al'brekht's Method

Arthur J. Krener

Department of Applied Mathematics, Naval Postgraduate School, Monterey, CA, USA

Abstract

A standard way of finding a feedback law that stabilizes a control system to an operating point is to recast the problem as an infinite horizon optimal control problem. If the optimal cost and the optimal feedback can be found on a large domain around the operating point, then a Lyapunov argument can be used to verify the asymptotic stability of the closed loop dynamics. The problem with this approach is that it is usually very difficult to find the optimal cost and the optimal feedback on a large domain for nonlinear problems with or even without constraints, hence the increasing interest in Model Predictive Control (MPC). In standard MPC a finite horizon optimal control problem is solved in real time, but just at the current state, the first control action is implemented, the system evolves one time step, and the process is repeated. A terminal cost and terminal feedback found by Al'brekht's method and defined in a neighborhood of the operating point can be used to shorten the horizon and thereby make the nonlinear programs easier to solve because they have less decision variables. Adaptive Horizon Model Predictive Control (AHMPC) is a scheme for varying the horizon length of Model Predictive Control as needed. Its goal is to achieve stabilization with horizons as small as possible so that MPC methods can be used on faster and/or more complicated dynamic processes.

Adaptive horizon · Model predictive control · Al'brekht's method · Optimal stabilization

Introduction

Model Predictive Control (MPC) is a way to steer a discrete time control system to a desired operating point. We will present an extension of MPC that we call Adaptive Horizon Model Predictive Control (AHMPC) which adjusts the length of the horizon in MPC while nearly verifying in real time that stabilization is occurring for a nonlinear system.

We are not the first to consider adaptively changing the horizon length in MPC; see Michalska and Mayne (1993), Polak and Yang (1993a, b, c). In these papers the horizon is changed so that a terminal constraint is satisfied by the predicted state at the end of horizon. In Giselsson (2010) the horizon length is adaptively changed to ensure that the infinite horizon cost of using the finite horizon MPC scheme is not much more than the cost of the corresponding infinite horizon optimal control problem.

Adaptive horizon tracking is discussed in Page et al. (2006) and Droge and Egerstedt (2011). In Kim and Sugie (2008) an adaptive parameter estimation algorithm suitable for MPC was proposed, which uses the available input and output signals to estimate the unknown system parameters. In Gruene et al. (2010) a detailed analysis of the impact of the optimization horizon and the time varying control horizon on stability and performance of the closed loop is given.

Review of Model Predictive Control

We briefly describe MPC following the definitive treatise of Rawlings and Mayne (2009). We largely follow their notation.

We are given a controlled, nonlinear dynamics in discrete time

$$x^+ = f(x, u) \quad (1)$$

where the state $x \in \mathbb{R}^{n \times 1}$, the control $u \in \mathbb{R}^{m \times 1}$, and $x^+(k) = x(k+1)$. Typically this a time discretization of a controlled, nonlinear dynamics in continuous time. The goal is to find a feedback law $u(k) = \kappa(x(k))$ that drives the

state of the system to some desired operating point. A pair (x^e, u^e) is an operating point if $f(x^e, u^e) = x^e$. We conveniently assume that, after state and control coordinate translations, the operating point of interest is $(x^e, u^e) = (0, 0)$.

The controlled dynamics may be subject to constraints such as

$$x \in \mathbb{X} \subset \mathbb{R}^{n \times 1} \quad (2)$$

$$u \in \mathbb{U} \subset \mathbb{R}^{m \times 1} \quad (3)$$

and possibly constraints involving both the state and control

$$y = h(x, u) \in \mathbb{Y} \subset \mathbb{R}^{p \times 1} \quad (4)$$

A control u is said to be feasible at $x \in \mathbb{X}$ if

$$u \in \mathbb{U}, f(x, u) \in \mathbb{X}, h(x, u) \in \mathbb{Y} \quad (5)$$

Of course the stabilizing feedback $\kappa(x)$ that we seek needs to be feasible, that is, for every $x \in \mathbb{X}$,

$$\kappa(x) \in \mathbb{U}, f(x, \kappa(x)) \in \mathbb{X}, h(x, \kappa(x)) \in \mathbb{Y}$$

An ideal way to find a stabilizing feedback is to choose a Lagrangian $l(x, u)$ (aka running cost), that is, nonnegative definite in x, u and positive definite in u , and then to solve the infinite horizon optimal control problem of minimizing the quantity

$$\sum_{k=0}^{\infty} l(x(k), u(k))$$

over all choices of infinite control sequences $\mathbf{u} = (u(0), u(1), \dots)$ subject to the dynamics (1), the constraints (2, 3, 4), and the initial condition $x(0) = x^0$. Assuming the minimum exists for each $x^0 \in \mathbb{X}$, we define the optimal cost function

$$V(x^0) = \min_u \sum_{k=0}^{\infty} l(x(k), u(k)) \quad (6)$$

Let $\mathbf{u}^* = (u^*(0), u^*(1), \dots)$ be a minimizing control sequence with corresponding state sequence $\mathbf{x}^* = (x^*(0) = x^0, x^*(1), \dots)$. Minimizing control and state sequences need

not be unique, but we shall generally ignore this problem because we are using optimization as a path to stabilization. The key question is whether the possibly nonunique solution is stabilizing to the desired operating point. As we shall see, AHMPC nearly verifies stabilization in real time.

If a pair $V(x) \in \mathbb{R}, \kappa(x) \in \mathbb{R}^{m \times 1}$ of functions satisfy the infinite horizon Bellman Dynamic Program Equations (BDP)

$$\begin{aligned} V(x) &= \min_u \{V(f(x, u)) + l(x, u)\} \\ \kappa(x) &= \operatorname{argmin}_u \{V(f(x, u)) + l(x, u)\} \end{aligned} \quad (7)$$

and the constraints

$$\kappa(x) \in \mathbb{U}, f(x, \kappa(x)) \in \mathbb{X}, h(x, \kappa(x)) \in \mathbb{Y} \quad (8)$$

for all $x \in \mathbb{X}$, then it is not hard to show that $V(x)$ is the optimal cost and $\kappa(x)$ is an optimal feedback on $\mathbb{X}$. Under suitable conditions a Lyapunov argument can be used to show that the feedback $\kappa(x)$ is stabilizing.

The difficulty with this approach is that it is generally impossible to solve the BDP equations on a large domain $\mathbb{X}$ if the state dimension n is greater than 2 or 3. So both theorists and practitioners have turned to Model Predictive Control (MPC).

In MPC one chooses a Lagrangian $l(x, u)$, a horizon length N , a terminal domain $\mathbb{X}_f \subset \mathbb{X}$ containing $x = 0$, and a terminal cost $V_f(x)$ defined and positive definite on $\mathbb{X}_f$. Then one considers the problem of minimizing

$$\sum_{k=0}^{N-1} l(x(k), u(k)) + V_f(x(N))$$

by choice of feasible

$$\mathbf{u}_N = (u_N(0), u_N(1), \dots, u_N(N-1))$$

subject to the dynamics (1), the constraints (8), the final condition $x(N) \in \mathbb{X}_f$, and the initial condition $x(0) = x^0$. Assuming this problem is solvable, let $V_N(x^0)$ denote the optimal cost

$$V_N(x^0) = \min_{u_N} \sum_{k=0}^{N-1} l(x(k), u(k)) + V_f(x(N)) \quad (9)$$

and let

$$\begin{aligned} u_N^* &= (u_N^*(0), u_N^*(1), \dots, u_N^*(N-1)) \\ x_N^* &= (x_N^*(0) = x^0, x_N^*(1), \dots, x_N^*(N)) \end{aligned}$$

denote optimal control and state sequences starting from x^0 when the horizon length is N . We then define the MPC feedback law $\kappa_N(x^0) = u_N^*(0)$.

The terminal set $\mathbb{X}_f$ is controlled invariant (aka viable) if for each $x \in \mathbb{X}_f$ there exists a $u \in \mathbb{U}$ such that $f(x, u) \in \mathbb{X}_f$ and $h(x, u) \in \mathbb{Y}$ are satisfied. If $V_f(x)$ is a control Lyapunov function on $\mathbb{X}_f$, then, under suitable conditions, a Lyapunov argument can be used to show that the feedback $\kappa_N(x)$ is stabilizing on $\mathbb{X}_f$. See Rawlings and Mayne (2009) for more details.

AHMPC requires a little more, the existence of terminal feedback $u = \kappa_f(x)$ defined on the terminal set $\mathbb{X}_f$ that leaves it positively invariant, if $x \in \mathbb{X}_f$ then $f(x, \kappa_f(x)) \in \mathbb{X}_f$, and which makes $V_f(x)$ a strict Lyapunov function on $\mathbb{X}_f$ for the closed loop dynamics, if $x \in \mathbb{X}_f$ and $x \neq 0$ then

$$V_f(x) > V_f(f(x, \kappa_f(x))) \geq 0$$

If $x \in \mathbb{X}_f$ then AHMPC does not need to solve (9) to get u , it just takes $u = \kappa_f(x)$. A similar scheme has been called dual mode control in Michalska and Mayne (1993).

The advantage of solving the finite horizon optimal control problem (9) over solving the infinite horizon problem (6) is that it may be possible to solve the former online as the process evolves. If it is known that the terminal set $\mathbb{X}_f$ can be reached from the current state x in N or fewer steps, then the finite horizon N optimal control problem is a feasible nonlinear program with finite dimensional decision variable $u_N \in \mathbb{R}^{m \times N}$. If the time step is long enough, if f, h, l are reasonably simple, and if N is small enough, then this nonlinear program possibly can be solved in

a fraction of one time step for u_N^* . Then the first element of this sequence $u_N^*(0)$ is used as the control at the current time. The system evolves one time step, and the process is repeated at the next time. Conceptually MPC computes a feedback law $\kappa_N(x) = u_N^*(0)$ but only at values of x when and where it is needed.

Some authors like Grimm et al. (2005) and Gruene (2012) do away with the terminal cost $V_f(x)$, but there is a theoretical reason and a practical reason to use one. The theoretical reason is that a control Lyapunov terminal cost facilitates a proof of asymptotic stability via a simple Lyapunov argument; see Rawlings and Mayne (2009). But this is not a binding reason because under suitable assumptions, asymptotic stability can be shown even when there is no terminal cost provided the horizon is sufficiently long. The practical reason is more important; when there is a terminal cost one can usually use a shorter horizon N . A shorter horizon reduces the dimension mN of the decision variables in the nonlinear programs that need to be solved online. Therefore MPC with a suitable terminal cost can be used for faster and more complicated systems.

An ideal terminal cost $V_f(x)$ is $V(x)$ of the corresponding infinite horizon optimal control provided that the latter can be accurately computed off-line on a reasonably large terminal set $\mathbb{X}_f$. For then the infinite horizon cost (6) and (9) will be the same. One should not make too much of this fact as stabilization is our goal; the optimal control problems are just a means to accomplish this. This in contrast to Economic MPC where the cost and the associated Lagrangian are chosen to model real-world costs.

Adaptive Horizon Model Predictive Control

For AHMPC we assume that we have the following;

- A discrete time dynamics $f(x, u)$ with operating point $x = 0, u = 0$.
- A Lagrangian $l(x, u)$, nonnegative definite in (x, u) and positive definite in u .

- State constraints $x \in \mathbb{X}$ where $\mathbb{X}$ is a neighborhood of $x = 0$.
- Control constraints $u \in \mathbb{U}$ where $\mathbb{U}$ is a neighborhood of $u = 0$.
- Mixed constraints $h(x, u) \in \mathbb{Y}$ which are not active at the operating point $x = 0, u = 0$.
- The dynamics is recursively feasible on $\mathbb{X}$, that is, for every $x \in \mathbb{X}$ there is a $u \in \mathbb{U}$ satisfying $h(x, u) \in \mathbb{Y}$ and $f(x, u) \in \mathbb{X}$.
- A terminal cost $V_f(x)$ defined and nonnegative definite on some neighborhood $\mathbb{X}_f$ of the operating point $x = 0, u = 0$. The neighborhood $\mathbb{X}_f$ need not be known explicitly.
- A terminal feedback $u = \kappa_f(x)$ defined on $\mathbb{X}_f$ such that the terminal cost is a valid Lyapunov function on $\mathbb{X}_f$ for the closed loop dynamics using the terminal feedback $u = \kappa_f(x)$.

One way of obtaining a terminal pair $V_f(x), \kappa_f(x)$ is to approximately solve the infinite horizon dynamic program equations (BDP) on some neighborhood of the origin. For example, if the linear part of the dynamics and the quadratic part of the Lagrangian constitute a linear quadratic regulator (LQR) problem satisfying the standard conditions, then one can let $V_f(x)$ be the quadratic optimal cost and $\kappa_f(x)$ be the linear optimal feedback of this LQR problem. Of course the problem with such terminal pairs $V_f(x), \kappa_f(x)$ is that generally there is no way to estimate the terminal set $\mathbb{X}_f$ on which the feasibility and Lyapunov conditions are satisfied. It is reasonable to expect that they are satisfied on some terminal set but the extent of this terminal set is difficult to estimate.

In the next section we show how higher degree Taylor polynomials for the optimal cost and optimal feedback can be computed by the discrete time extension (Aguilar and Krener 2012) of Al'brekht's method (Al'brecht 1961) because this can lead to a larger terminal set $\mathbb{X}_f$ on which the feasibility and the Lyapunov conditions are satisfied. It would be very difficult to determine what this terminal set is, but fortunately in AHMPC we do not need to do this.

AHMPC mitigates this last difficulty just as MPC mitigates the problem of solving the infinite horizon Bellman Dynamic Programming

equations BDP (7). MPC does not try to compute the optimal cost and optimal feedback everywhere; instead it computes them just when and where they are needed. AHMPC does not try to compute the set $\mathbb{X}_f$ on which $\kappa_f(x)$ is feasible and stabilizing; it just tries to determine if the end state $x_N^*(N)$ of the currently computed optimal trajectory is in a terminal set $\mathbb{X}_f$ where the feasibility and Lyapunov conditions are satisfied.

Suppose the current state is x and we have solved the horizon N optimal control problem for $u_N^* = (u_N^*(0), \dots, u_N^*(N-1))$, $x_N^* = (x_N^*(0) = x, \dots, x_N^*(N))$. The terminal feedback $u = \kappa_f(x)$ is used to compute M additional steps of this state trajectory

$$x_N^*(k+1) = f(x_N^*(k), \kappa_f(x_N^*(k))) \quad (10)$$

for $k = N, \dots, N+M-1$.

Then one checks that the feasibility and Lyapunov conditions hold for the extended part of the state sequence,

$$\kappa_f(x_N^*(k)) \in \mathbb{U} \quad (11)$$

$$f(x_N^*(k), \kappa_f(x_N^*(k))) \in \mathbb{X} \quad (12)$$

$$h(x_N^*(k), \kappa_f(x_N^*(k))) \in \mathbb{Y} \quad (13)$$

$$V_f(x_N^*(k)) \geq \alpha(|x_N^*(k)|) \quad (14)$$

$$V_f(x_N^*(k)) - V_f(x_N^*(k+1)) \geq \alpha(|x_N^*(k)|) \quad (15)$$

for $k = N, \dots, N+M-1$ and some Class K function $\alpha(s)$. For more on Class K functions, we refer the reader to Khalil (1996).

If (11–15) hold for all for $k = N, \dots, N+M-1$, then we presume that $x_N^*(N) \in \mathbb{X}_f$, a set where $\kappa_f(x)$ is stabilizing and we use the control $u_N^*(0)$ to move one time step forward to $x^+ = f(x, u_N^*(0))$. At this next state x^+ , we solve the horizon $N-1$ optimal control problem and check that the extension of the new optimal trajectory satisfies (11–15).

If (11–15) does not hold for all for $k = N, \dots, N+M-1$, then we presume that $x_N^*(N) \notin \mathbb{X}_f$. We extend current horizon N

to $N + L$ where $L \geq 1$, and if time permits, we solve the horizon $N + L$ optimal control problem at the current state x and then check the feasibility and Lyapunov conditions again. We keep increasing N by L until these conditions are satisfied on the extension of the trajectory. If we run out of time before they are satisfied, then we use the last computed $u_N^*(0)$ and move one time step forward to $x^+ = f(x, u_N^*(0))$. At x^+ we solve the horizon $N + L$ optimal control problem.

How does one choose the extended horizon M and the class K function $\alpha(\cdot)$? If the extended part of the state sequence is actually in the region where the terminal cost $V_f(x)$ and the terminal feedback $\kappa_f(x)$ well approximate the solution to infinite horizon optimal control problem, then the dynamic programming equations (7) should approximately hold. In other words

$$\begin{aligned} V_f(x_N^*(k)) - V_f(x_N^*(k+1)) \\ \approx l(x_N^*(k), \kappa_f(x_N^*(k))) \geq 0 \end{aligned}$$

If this does not hold throughout the extended trajectory, we should increase the horizon N . We can also increase the extended horizon M , but this may not be necessary. If the Lyapunov and feasibility conditions are going to fail somewhere on the extension, it is most likely this will happen at the beginning of the extension. Also we should choose $\alpha(\cdot)$ so that $\alpha(|x|) < |l(x, \kappa_f(x))|/2$.

The nonlinear programming problems generated by employing MPC on a nonlinear system are generally nonconvex so the solver might return local rather than global minimizers. In which case there is no guarantee that an MPC approach is actually stabilizing. AHMPC mitigates this difficulty by nearly checking that stabilization is occurring. If (11–15) don't hold even after the horizon N has been increased substantially, then this is a strong indication that the solver is returning locally rather than globally minimizing solutions, and these local solutions are not stabilizing. To change this behavior one needs to start the solver at a substantially different initial guess. Just how one does this is an open research question. It is essentially the same ques-

tion as which initial guess should one pass to the solver at the first step of MPC.

The actual computation of the M additional steps (10) can be done very quickly because the closed loop dynamics function $f(x, \kappa_f(x))$ can be computed and compiled beforehand. Similarly the feasibility and Lyapunov conditions (11–15) can be computed and compiled beforehand. The number M of additional time steps is a design parameter. One choice is to take M a positive integer; another choice is a positive integer plus a fraction of the current N .

Choosing a Terminal Cost and a Terminal Feedback

A standard way of obtaining a terminal cost $V_f(x)$ and a terminal feedback $\kappa_f(x)$ is to solve the linear quadratic regulator (LQR) using the quadratic part of the Lagrangian and the linear part of dynamics around the operating point $(x^e, u^e) = (0, 0)$. Suppose

$$\begin{aligned} l(x, u) &= \frac{1}{2} (x' Q x + 2x' S u + u' R u) + O(x, u)^3 \\ f(x, u) &= Fx + Gu + O(x, u)^2 \end{aligned}$$

Then the LQR problem is to find P, K such that

$$\begin{aligned} P &= F' P F - (F' P G + S) \\ &\quad (R + G' P G)^{-1} (G' P F + S') + Q \end{aligned} \quad (16)$$

$$K = -(R + G' P G)^{-1} (G' P F + S') \quad (17)$$

Under mild assumptions, the stabilizability of F, G , the detectability of $Q^{1/2}, F$, the nonnegative definiteness of $[Q, S; S', R]$, and the positive definiteness of R , there exist a unique nonnegative definite P satisfying the first equation (16) which is called the discrete time algebraic Riccati equation (DARE). Then K given by (17) puts all the poles of the closed loop linear dynamics

$$x^+ (F + GK) x$$

inside of the open unit disk. See Antsaklis and Michel (1997) for details. But $l(x, u)$ is a design parameter so we choose $[Q, S; S', R]$ to be positive definite and then P will be positive definite.

If we define the terminal cost to be $V_f(x) = \frac{1}{2}x'Px$, then we know that it is positive definite for all $x \in \mathbb{R}^{n \times 1}$. If we define the terminal feedback to be $\kappa_f(x) = Kx$, then we know by a Lyapunov argument that the nonlinear closed loop dynamics

$$x^+ = f(x, \kappa(x))$$

is locally asymptotically stable around $x^e = 0$. The problem is that we don't know what is the neighborhood $\mathbb{X}_f$ of asymptotic stability and computing it off-line can be very difficult in state dimensions higher than two or three.

There are other possible choices for the terminal cost and terminal feedback. Al'brecht (1961) showed how the Taylor polynomials of the optimal cost and the optimal feedback could be computed for some smooth, infinite horizon optimal control problems in continuous time. Aguilar and Krener (2012) extended this to some smooth, infinite horizon optimal control problems in discrete time. The discrete time Taylor polynomials of the optimal cost and the optimal feedback may be used as the terminal cost and terminal feedback in an AHMPC scheme, so we briefly review (Aguilar and Krener 2012).

Since we assumed that $f(x, u)$ and $l(x, u)$ are smooth and the constraints are not active at the origin, we can simplify the BDP equations. The simplified Bellman Dynamic Programming equations (sBDP) are obtained by setting the derivative with respect to u of the quantity to be minimized in (7) to zero. The result is

$$V(x) = V(f(x, \kappa(x))) + l(x, \kappa(x)) \quad (18)$$

$$0 = \frac{\partial V}{\partial x}(f(x, u)) \frac{\partial f}{\partial u}(x, \kappa(x)) + \frac{\partial l}{\partial u}(x, \kappa(x)) \quad (19)$$

If the quantity to be minimized is strictly convex in u , then the BDP equations and sBDP equations

are equivalent. But if not then BDP implies sBDP but not vice versa.

Suppose the discrete time dynamics and Lagrangian have Taylor polynomials around the operating point $x = 0, u = 0$ of the form

$$\begin{aligned} f(x, u) &= Fx + Gu + f^{[2]}(x, u) \\ &\quad + \dots + f^{[d]}(x, u) + O(x, u)^{d+1} \\ l(x, u) &= \frac{1}{2}(x'Qx + 2x'Su + u'Ru) + l^{[3]}(x, u) \\ &\quad + \dots + l^{[d+1]}(x, u) + O(x, u)^{d+2} \end{aligned}$$

for some integer $d \geq 1$ where $^{[j]}$ indicates the homogeneous polynomial terms of degree j .

Also suppose the infinite horizon optimal cost and optimal feedback have similar Taylor polynomials

$$\begin{aligned} V(x) &= \frac{1}{2}x'Px + V^{[3]}(x) + \dots \\ &\quad + V^{[d+1]}(x) + O(x, u)^{d+2} \\ \kappa(x) &= Kx + \kappa^{[2]}(x, u) + \dots \\ &\quad + \kappa^{[d]}(x, u) + O(x, u)^{d+1} \end{aligned}$$

We plug these polynomials into sBDP and collect terms of lowest degree. The lowest degree in (18) is two while in (19) it is one. The result is the discrete time Riccati equations (16, 17).

At the next degrees we obtain the equations

$$\begin{aligned} V^{[3]}(x) &= V^{[3]}((F + GK)x) \\ &= ((F + GK)x)' P f^{[2]}(x, Kx) \\ &\quad + l^{[3]}(x, Kx) \end{aligned} \quad (20)$$

$$\begin{aligned} &\left(\kappa^{[2]}(x) \right)' (R + G'PG) \\ &= -\frac{\partial V^{[3]}}{\partial x}((F + GK)x)G \\ &\quad - ((F + GK)x)' P \frac{\partial f^{[2]}}{\partial u}(x, Kx) \\ &\quad - \frac{\partial l^{[3]}}{\partial u}(x, Kx) \end{aligned} \quad (21)$$

Notice these are linear equations in the unknowns $V^{[3]}(x)$ and $\kappa^{[2]}(x)$ and the right sides of these equations involve only known quantities. Moreover $\kappa^{[2]}(x)$ does not appear in the first equation. The mapping

$$V^{[3]}(x) \mapsto V^{[3]}(x) - V^{[3]}((F + GK)x) \quad (22)$$

is a linear operator on the space of polynomials of degree three in x . Its eigenvalues are of the form of 1 minus the products of three eigenvalues of $F + GK$. Since the eigenvalues of $F + GK$ are all inside the open unit disk, zero is not an eigenvalue of the operator (22), so it is invertible. Having solved (20) for $V^{[3]}(x)$, we can readily solve (21) for $\kappa^{[2]}(x)$ since we have assumed R is positive definite

The higher degree equations are similar, at degrees $d + 1, d$ they take the form

$$\begin{aligned} & V^{[j+1]}(x) - V^{[j+1]}((F + GK)x) \\ &= \text{Known Quantities} \\ & \left(\kappa^{[j]}(x) \right)' (R + G'PG) \\ &= \text{Known Quantities} \end{aligned}$$

The “Known Quantities” involve the terms of the Taylor polynomials of f, l and previously computed $V^{[i+1]}, \kappa^{[i]}$ for $1 \leq i < j$. Again the equations are linear in the unknowns $V^{[k+1]}, \kappa^{[k]}$, and the first equation does not involve $\kappa^{[k]}$. The eigenvalues of the linear operator

$$V^{[k+1]}(x) \mapsto V^{[k+1]}(x) - V^{[k+1]}((F + GK)x)$$

are of the form of 1 minus the products of $k + 1$ eigenvalues of $F + GK$.

We have written MATLAB code to solve these equations to any degree and in any dimensions. The code is quite fast. Later we shall present an example where $n = 4$ and $m = 2$. The code found the Taylor polynomials of the optimal cost to degree 6 and the optimal feedback to degree 5 in 0.12 s. on a laptop using 3.1 GHz Intel Core i5.

Completing the Squares

The infinite horizon optimal cost is certainly non-negative definite, and if we choose $Q > 0$ then it is positive definite. That implies that its quadratic part $V^{[2]}(x) = \frac{1}{2}x'Px$ is positive definite.

But its Taylor polynomial of degree $d + 1$,

$$V^{[2]}(x) + V^{[3]}(x) + \dots + V^{[d+1]}(x)$$

need not be positive definite for $d > 1$. This can lead to problems if we define this Taylor polynomial to be our terminal cost $V_f(x)$ because then the nonlinear program solver might return a negative cost $V_N(x)$ (9). The way around this difficulty is to “complete the squares.”

Theorem Suppose a polynomial $V(x)$ is of degrees two through $d + 1$ in n variables $x_1, \dots, x_n$. If the quadratic part of $V(x)$ is positive definite, then there exist a nonnegative definite polynomial $W(x)$ of degrees two through $2d$ such that the part of $W(x)$ that is of degrees two through $d + 1$ equals $V(x)$. Moreover, we know that $W(x)$ is nonnegative definite because it is the sum of n squares.

Proof. We start with the quadratic part of $V(x)$, because it is positive definite it must be of the form $\frac{1}{2}x'Px$ where P is a positive definite $n \times n$ matrix. We know that there is an orthogonal matrix T that diagonalizes P

$$T'PT = \begin{bmatrix} \lambda_1 & & 0 \\ & \ddots & \\ 0 & & \lambda_n \end{bmatrix}$$

where $\lambda_1 \geq \lambda_2 \geq \dots \geq \lambda_n > 0$. We make the linear change of coordinates $x = Tz$. We shall show that $V(z) = V(Tz)$ can be extended with higher degree terms to a polynomial $W(z)$ of degrees two through $2d$ which is a sum of n squares. We do this degree by degree. We have already showed that the degree two part of $V(z)$ is a sum of n squares

$$\frac{1}{2} \sum_{i=1}^n \lambda_i z_i^2 = \frac{1}{2} (\lambda_1 z_1^2 + \dots + \lambda_n z_n^2)$$

The degrees two and three parts of $V(z)$ are of the form

$$\frac{1}{2} \sum_{i=1}^n \lambda_i z_i^2 + \sum_{i_1=1}^n \sum_{i_2=i_1}^n \sum_{i_3=i_2}^n \gamma_{i_1, i_2, i_3} z_{i_1} z_{i_2} z_{i_3}$$

Consider the expression

$$\delta_1(z) = z_1 + \sum_{i_2=1}^n \sum_{i_3=i_2}^n \delta_{1, i_2, i_3} z_{i_2} z_{i_3}$$

then

$$\begin{aligned} \frac{\lambda_1}{2} (\delta_1(z))^2 &= \frac{\lambda_1}{2} \left(z_1 + \sum_{i_2=1}^n \sum_{i_3=i_2}^n \delta_{1, i_2, i_3} z_{i_2} z_{i_3} \right)^2 \\ &= \frac{\lambda_1}{2} \left(z_1^2 + 2 \sum_{i_2=1}^n \sum_{i_3=i_2}^n \delta_{1, i_2, i_3} z_1 z_{i_2} z_{i_3} + \frac{1}{2} \left(\sum_{i_2=1}^n \sum_{i_3=i_2}^n \delta_{1, i_2, i_3} z_{i_2} z_{i_3} \right)^2 \right) \end{aligned}$$

Let $\delta_{1, i_2, i_3} = \frac{\gamma_{1, i_2, i_3}}{\lambda_1}$ then the degrees two and three parts of

$$V(z) - \frac{\lambda_1}{2} (\delta_1(z))^2$$

have no terms involving z_1 .

□

Next consider the expression

$$\delta_2(z) = z_2 + \sum_{i_2=2}^n \sum_{i_3=i_2}^n \delta_{2, i_2, i_3} z_{i_2} z_{i_3}$$

then

$$\begin{aligned} \frac{\lambda_2}{2} (\delta_2(z))^2 &= \frac{\lambda_2}{2} \left(z_2^2 + 2 \sum_{i_2=2}^n \sum_{i_3=i_2}^n \delta_{2, i_2, i_3} z_2 z_{i_2} z_{i_3} \right. \\ &\quad \left. + \frac{1}{2} \left(\sum_{i_2=2}^n \sum_{i_3=i_2}^n \delta_{2, i_2, i_3} z_{i_2} z_{i_3} \right)^2 \right) \end{aligned}$$

Let $\delta_{2, i_2, i_3} = \frac{\gamma_{2, i_2, i_3}}{\lambda_2}$ then the degrees two and three parts of

$$V(z) - \frac{\lambda_1}{2} (\delta_1(z))^2 - \frac{\lambda_2}{2} (\delta_2(z))^2$$

have no terms involving either z_1 or z_2 .

We continue on in this fashion defining $\delta_3(z), \dots, \delta_n(z)$ such that

$$V(z) - \sum_{i=1}^n \frac{\lambda_i}{2} (\delta_i(z))^2 = \sum_{i_1=1}^n \sum_{i_2=i_1}^n \sum_{i_3=i_2}^n \sum_{i_4=i_3}^n \gamma_{i_1, i_2, i_3, i_4} z_{i_1} z_{i_2} z_{i_3} z_{i_4} + O(z)^5$$

has no terms of degrees either two or three.

We redefine

$$\begin{aligned} \delta_1(z) &= z_1 + \sum_{i_2=1}^n \sum_{i_3=i_2}^n \delta_{1, i_2, i_3} z_{i_2} z_{i_3} \\ &\quad + \sum_{i_2=1}^n \sum_{i_3=i_2}^n \sum_{i_4=i_3}^n \delta_{1, i_2, i_3, i_4} z_{i_2} z_{i_3} z_{i_4} \end{aligned}$$

This does not change the degree two and three terms of $\frac{\lambda_1}{2} (\delta_1(z))^2$, and its degree four terms are of the form

$$\lambda_1 \sum_{i_2=1}^n \sum_{i_3=i_2}^n \sum_{i_4=i_3}^n \delta_{1, i_2, i_3, i_4} z_1 z_{i_2} z_{i_3} z_{i_4}$$

If we let $\delta_{1,i_2,i_3,i_4} = \frac{\gamma_{1,i_2,i_3,i_4}}{\lambda_1}$, then we cancel the degree four terms involving z_1 in

$$V(z) - \sum_{j=1}^n \frac{\lambda_j}{2} (\delta_j(z))^2$$

Next we redefine

$$\begin{aligned} \delta_2(z) = & z_2 + \sum_{i_2=2}^n \sum_{i_3=i_2}^n \delta_{2,i_2,i_3} z_{i_2} z_{i_3} \\ & + \sum_{i_2=2}^n \sum_{i_3=i_2}^n \sum_{i_4=i_3}^n \delta_{2,i_2,i_3,i_4} z_{i_2} z_{i_3} z_{i_4} \end{aligned}$$

Again this does not change the degree two and three terms of $\frac{\lambda_2}{2} (\delta_2(z))^2$, and its degree four terms are of the form

$$\lambda_2 \sum_{i_2=2}^n \sum_{i_3=i_2}^n \sum_{i_4=i_3}^n \delta_{2,i_2,i_3,i_4} z_{i_2} z_{i_3} z_{i_4}$$

If we let $\delta_{2,i_2,i_3,i_4} = \frac{\gamma_{2,i_2,i_3,i_4}}{\lambda_2}$ then we cancel the degree four terms involving z_2 in

$$V(z) - \sum_{j=1}^n \frac{\lambda_j}{2} (\delta_j(z))^2$$

We continue on in this fashion. The result is a sum of squares whose degree two through four terms equal $V(z)$.

Eventually we define

$$\begin{aligned} \delta_j(z) = & z_j + \sum_{i_2=j}^n \sum_{i_3=i_2}^n \delta_{j,i_2,i_3} z_{i_2} z_{i_3} + \cdots \\ & + \sum_{i_2=j}^n \cdots \sum_{i_d=i_{d-1}}^n \delta_{j,i_2,\dots,i_d} z_{i_2} \cdots z_{i_d} \end{aligned}$$

and

$$W(z) = \sum_{j=1}^n \frac{\lambda_j}{2} (\delta_j(z))^2$$

At degree $d = 3$, we solved a linear equation from the quadratic coefficients of $\delta_1(z), \dots, \delta_n(z)$

to the cubic coefficients of $V(z)$. We restricted the domain of this mapping by requiring that the quadratic part of $\delta_i(z)$ does not depend on $z_1, \dots, z_{i-1}$. This made the restricted mapping square; the dimensions of the domain and the range of the linear mapping are the same. We showed that the restricted mapping has a unique solution.

If we drop this restriction, then at degree d the overall dimension of the domain is

$$n \binom{n+d-1}{d}$$

while the dimension of the range is

$$\binom{n+d}{d+1}$$

So the unrestricted mapping has more unknowns than equations, and hence there are multiple solutions.

But the restricted solution that we constructed is a least squares solution to the unrestricted equations because $\lambda_1 \geq \lambda_2 \geq \dots \geq \lambda_n > 0$. To see this consider the coefficient $\gamma_{1,1,2}$ of $z_1^2 z_2$. If we allow $\gamma_2(z)$ to have a term of the form $\delta_{2,1,1} z_1^2$, we can also cancel $\gamma_{1,1,2}$ by choosing $\delta_{1,1,2}$ and $\delta_{2,1,1}$ so that

$$\gamma_{1,1,2} = \lambda_1 \delta_{1,1,2} + \lambda_2 \delta_{2,1,1}$$

Because $\lambda_1 \geq \lambda_2$, a least squares solution to this equation is $\delta_{1,1,2} = \frac{\gamma_{1,1,2}}{\lambda_1}$ and $\delta_{2,1,1} = 0$. Because T is orthogonal, $W(x) = W(T'z)$ is also a least squares solution.

Example

Suppose we wish to stabilize a double pendulum to straight up. The first two states are the angles between the two links and straight up measured in radians counterclockwise. The other two states are their angular velocities. The controls are the torques applied at the base of the lower link and at the joint between the links. The links are assumed to be massless, the base link is one meter long,

and the other link is two meters long. There is a mass of two kilograms at the joint between the links and a mass of one kilogram at the tip of the upper link. There is linear damping at the base and the joint with both coefficients equal to 0.5 s^{-1} . The resulting continuous time dynamics is discretized using Euler's method with time step 0.1 s .

We simulated AHMPC with two different terminal costs and terminal feedbacks. In both cases the Lagrangian was

$$\frac{0.1}{2} (|x|^2 + |u|^2) \quad (23)$$

The first pair $V_f^2(x), \kappa_f^1(x)$ was found by solving the infinite horizon LQR problem obtained by taking the linear part of the dynamics around the operating point $x = 0$ and the quadratic Lagrangian (23). Then $V_f^2(x)$ is quadratic and positive definite and $\kappa_f^1(x)$ is a linear.

The second pair $V_f^6(x), \kappa_f^5(x)$ was found using the discrete time version of Al'brekht's method. Then $V_f^6(x)$ is the Taylor polynomial of the optimal cost to degree 6 and $\kappa_f^5(x)$ is the Taylor polynomial of the optimal feedback to degree 5. But $V_f^6(x)$ is not positive definite so we completed the squares as above to get degree 10 polynomial $V_f^{10}(x)$ which is positive definite.

In all the simulations we imposed the control constraint $|u|_\infty \leq 4$ and started at $x(0) = (0.9\pi, 0.9\pi, 0, 0)$ with an initial horizon of $N =$

50 time steps. The extended horizon was kept constant at $M = 5$. The class K function was taken to be $\alpha(s) = s^2/10$.

If the Lyapunov or feasibility conditions were violated, then the horizon N was increased by 5 and the finite horizon nonlinear program was solved again without advancing the system. If after three tries the Lyapunov or feasibility conditions were still not satisfied, then the first value of the control sequence was used, the simulation was advanced one time step, and the horizon was increased by 5 (Fig. 1).

If the Lyapunov and feasibility conditions were satisfied over the extended horizon, then the simulation was advanced one time step, and the horizon N was decreased by 1.

The simulations were first run with no noise, and the results are shown in the following figures. Both methods stabilized the links to straight up in about $t = 80$ times steps (8 s). The degree $2d = 10$ terminal cost and the degree $d = 5$ terminal feedback seem to do it a little more smoothly with no overshoot and with shorter maximum horizon $N = 65$ versus $N = 75$ for LQR ($d = 1$) (Fig. 2).

The simulations were done on a MacBook Pro with a 3.1 GHz Intel Core i5 using MATLAB's `fmincon.m` with its default settings. We did supply `fmincon.m` the gradients of the objective functions, but we did not give it the Hessians. The cpu time for the degree $2d = 10$ terminal cost and the degree $d = 5$ terminal feedback was 5.01 s. This is probably too slow to control

Adaptive Horizon Model Predictive Control and Al'brekht's Method, Fig. 1 Angles, $d = 1$ on left, $d = 5$ on right

Adaptive Horizon Model Predictive Control and Al'brekht's Method, Fig. 2 Controls, $d = 1$ on left, $d = 5$ on right

pendulum in real time because the solver needs to return $u^*(0)$ in a fraction of a time step. But by using a faster solver than `fmincon.m`, coding the objective, the gradient, and the Hessian in C and compiling them, we probably could control the double pendula in real time. The CPU time for the LQR terminal cost and terminal feedback was 24.56 s so it is probably not possible to control the double pendula in real time using LQR terminal cost and terminal feedback (Fig. 3). Then we added noise to the simulations. At each advancing step a Gaussian random vector with mean zero and covariance 0.0001 times the identity was added to the state. The next figures show the results using the degree 10 terminal cost and degree 5 terminal feedback. Notice that the horizon starts at $T = 50$ but immediately jumps to $T = 65$, declines to $T = 64$, then jumps to $T = 69$ before decaying monotonically to zero. When the horizon $T = 0$ the terminal feedback is used. The LQR terminal cost and feedback failed to stabilize the noisy pendula. We stopped the simulation when $T > 1000$ (Fig. 4).

We also considered $d = 3$ so that after completing the squares the terminal cost is degree $2d = 6$ and the terminal feedback is degree $d = 3$. It stabilized the noiseless simulation with a maximum horizon of $N = 80$ which is greater than the maximum horizons for both $d = 1$ and $d = 5$. But it did not stabilize the noisy simulation. Perhaps the reason is revealed by Taylor polynomial approximations to $\sin x$ as

shown in Figure 5. The linear approximation in green overestimates the magnitude of $\sin x$, so the linear feedback is stronger than it needs to be to overcome gravity. The cubic approximation in blue underestimates the magnitude of $\sin x$ so the cubic feedback is weaker than it needs to be to overcome gravity. The quintic approximation in orange overestimates the magnitude of $\sin x$, so the quintic feedback is also stronger than it needs to be but by a lesser margin than the linear feedback to overcome gravity. This may explain why the degree 5 feedback stabilizes the noise free pendula in a smoother fashion than the linear feedback (Fig. 5).

Conclusion

Adaptive Horizon Model Predictive Control is a scheme for varying the horizon length in Model Predictive Control as the stabilization process evolves. It adapts the horizon in real time by testing Lyapunov and feasibility conditions on extensions of optimal trajectories returned by the nonlinear program solver. In this way it seeks the shortest horizons consistent with stabilization.

AHMPC requires a terminal cost and terminal feedback that stabilizes the plant in some neighborhood of the operating point but that neighborhood need not be known explicitly. Higher degree Taylor polynomial approximations to the optimal cost and the optimal feedback of the cor-

Adaptive Horizon Model Predictive Control and Al'brekht's Method, Fig. 4 Noisy angles, controls and horizons

Adaptive Horizon Model Predictive Control and Al'brekht's Method,

Fig. 5 Taylor approximations to $y = \sin x$

responding infinite horizon optimal control problems can be found by an extension of Al'brekht's method (Aguilar and Krener 2012). The higher degree Taylor polynomial approximations to optimal cost need not be positive definite, but they can be extended to nonnegative definite polynomials by completing the squares. These nonnegative definite extensions and the Taylor polynomial approximations to the optimal feedback can be used as terminal costs and terminal feedbacks in AHMPC. We have shown by an example that a higher degree terminal cost and feedback can outperform using LQR to define a degree two terminal cost and a degree one terminal feedback.

Adaptive Human Pilot Models for Aircraft Flight Control

Ronald A. Hess
University of California, Davis, CA, USA

Abstract

Loss-of-control incidents in commercial and military aircraft have prompted a renewed interest in the manner in which the human pilot adapts to sudden changes or anomalies in the flight control system which augments the fundamental aircraft dynamics. A simplified control-theoretic model of the human pilot can be employed to describe adaptive pilot behavior in the so-called primary control loops and to shed light upon the limits of human control capabilities.

Keywords

Control-theoretic pilot models · Pilot crossover model · Aircraft loss of control · Single and multi-axis pilot control

An Introduction to Control-Theoretic Models of the Human Pilot

A control-theoretic model of the human pilot refers to a representation in which the pilot is modeled as an element in a control system. Typically, this means that the dynamics of the pilot are represented by a transfer function, and this transfer function is placed in a block diagram where the pilot's control inputs affect the aircraft's responses. In its simplest form, such a representation is shown in Fig. 1.

As a more concrete representation, “command” might indicate a command to the pilot/aircraft system in the form of a desired aircraft pitch attitude. “Control” might represent an aircraft elevator motion produced by the pilot, whose dynamics are represented by the linear, time-invariant transfer function $Y_p(s)$. “Controlled element” is the pertinent aircraft transfer function, $Y_c(s)$ representing the manner in which aircraft pitch attitude (“response”) is dependent upon the pilot's control input.

Perhaps the most definitive representation of human pilot dynamics in tasks such as that shown in Fig. 1 is the “crossover” model of the combined human pilot and controlled element (McRuer and Krendel 1974), shown in Eq. 1.

$$Y_p(s)Y_c(s) \approx \omega_c \frac{e^{-\tau_e s}}{s} \quad (1)$$

This is called the *crossover model* of the human pilot because it is a neighborhood of the frequency region where $|Y_p(j\omega)Y_c(j\omega)| \approx 1.0$, where the model is valid. Figure 2 shows a typical measured $Y_p Y_c(s)$ plotted on a Bode diagram and compared to the crossover model. The controlled element dynamics in this case were $Y_c = K_c/s$ (McRuer et al. 1965). The phase lags apparent for $\omega > \omega_c$ are attributable to the time delay τ_e in Eq. 1 and limit the magnitude of an open-loop crossover frequency for stable closed-loop operation of the pilot/aircraft system.

A more complete discussion of linear, time-invariant control-theoretic models of the human pilot can be found in Hess (1997).

Adaptive Human Pilot Models for Aircraft Flight Control, Fig. 1 A block diagram of a control-theoretic model of the human pilot in a single-loop tracking task. Both Y_p and Y_c are represented by transfer functions

Adaptive Human Pilot Models for Aircraft Flight Control,

Fig. 2 A Bode diagram of the measured $Y_p Y_c$ in a single-loop tracking task is shown. In this example, $Y_c = K_c/s$

A Simplified Pursuit Control Model of the Human Pilot

Pilot control behavior in command-following tracking tasks is often categorized as either *compensatory* or *pursuit* depending upon the type of visual information available to the pilot (Krendel and McRuer 1960; Hess 1981). Figure 3 compares two cockpit displays, one providing

compensatory information (error only) and one providing pursuit information (command and error). Figure 4 is a block diagram representation of the pursuit tracking pilot model to be utilized herein (Hess 2006).

It should be emphasized that the analysis procedure to be described utilizes a sequential loop closure formulation for piloted control. For example, in Fig. 1 the command or input may

Adaptive Human Pilot Models for Aircraft Flight Control, Fig. 3 Two cockpit displays can be created showing the difference between compensatory and pursuit tracking formats

Adaptive Human Pilot Models for Aircraft Flight Control, Fig. 4 A pursuit tracking model of the human pilot from Hess (2006). In pursuit tracking behavior, vehicle

output and output rate are assumed to be directly available to the pilot, here represented by K_p , K_r , and G_{nm}

be an altitude command in which the pilot is using pitch attitude as a primary loop closure to control aircraft altitude. The element denoted G_{nm} in Fig. 4 represents the simplified dynamics of the neuromuscular system driving the cockpit inceptor. Further information on neuromuscular system models can be found in McRuer and Magdalenio (1966). In the model of Fig. 4, G_{nm} is given by

$$G_{nm} = \frac{10^2}{s^2 + 2(707)s + 10^2} \quad (2)$$

Figure 5 shows the manner in which Fig. 4 can be expanded to include such sequential closures. In Fig. 5, the “vehicle with primary loop closed” would simply be the M/C transfer function in Fig. 4. As discussed in Hess (2006),

the adjustment rules for selecting K_{ro} and K_{po} are as follows: K_{ro} is chosen as the gain value that results in a crossover frequency for the transfer function $K_{ro} \cdot [\dot{M}_o/C]$ equal to that for the adjacent inner loop and M/E in Fig. 4. K_{po} is chosen to provide a desired open-loop crossover frequency in the outer-loop transfer function M_o/E_o . Nominally, this crossover frequency will be one-third the value for the crossover frequency in the inner loop of Fig. 4.

A distinct advantage of the pilot model of Fig. 4 lies in the fact that only two parameters, the gains K_p and K_r , are necessary to implement the model in a primary control loop. Hess (2006) demonstrates the manner in which this is accomplished. Basically, K_r is chosen so that the Bode diagram of the transfer function $\frac{\dot{M}}{R}(s)$ exhibits a 10 dB amplitude peaking near 10 rad/s. K_p is

Adaptive Human Pilot Models for Aircraft Flight Control, Fig. 5 A multi-loop extension of the pilot model of Fig. 4. The block “vehicle with primary loop closed”

implies that the pilot model of Fig. 4 has been used in a primary-loop closure

then chosen to yield a 2.0 rad/s crossover frequency in the Bode diagram of $\frac{M}{C}(s)$. Hess (2006) demonstrates the ability of the two-parameter pilot model to reproduce pilot crossover model characteristics for a variety of vehicle dynamics in Fig. 4. The fact that only two gain values are necessary to create the pilot model suggests that extending the representation of Fig. 4 to encompass adaptive pilot behavior may be warranted.

A Rationale for Modeling the Adaptive Human Pilot

Loss of control is the leading cause of jet fatalities worldwide (Jacobson 2010). Aside from their frequency of occurrence, aviation accidents resulting from loss of control seize the public’s attention by yielding large number of fatalities in a single event. The rationale for modeling the human pilot in potential loss of control accidents can be best summarized as follows (McRuer and Jex 1967):

- (1) To summarize behavioral data
- (2) To provide a basis for rationalization and understanding of pilot control actions
- (3) To be used in conjunction with vehicle dynamics in forming predictions or in explaining the behavior of pilot-vehicle systems

To this list might be added: to be used in concert with human-in-the-loop flight simulation to offer a fundamental rationale for aircraft loss of control.

Modeling the Adaptive Human Pilot

Studies devoted to modeling the human pilot’s adaptive capabilities date from the mid-1960s. See, for example, Elkind and Miller (1966), Weir (1968), Young (1969), Niemela and Krendel (1974), and Hess (2016). As used herein, “adaptive behavior” will refer to the human pilot’s ability to adopt dynamic characteristics that allow control of sudden changes in the dynamics of the aircraft being controlled. This is in contrast to a human “learning” to control a dynamic system through a training process. Figure 6 from Hess (2016) shows the fundamental adaptive structure of the adaptive human pilot in a primary control loop.

In Hess (2016) the adaptive logic governing changes in K_p and K_r are defined. The reader is referred to that document for specifics. The logic is based upon certain guidelines:

- (1) The adjustments to K_p and K_r must be predicated upon observations that can easily be made by the human pilot.
- (2) The logic driving the adjustments must be predicated on information available to the human pilot.
- (3) The post-adapted pilot models must follow the dictates of the crossover model of the human pilot (McRuer and Krendel 1974).
- (4) Performance improvement with adaptation must occur relatively quickly. This guideline is supported by the research reported by Hess (2009).

Adaptive Human Pilot Models for Aircraft Flight Control, Fig. 6 Modifying the model of Fig. 4 to enable modeling of pilot adaptive behavior

Adaptive Human Pilot Models for Aircraft Flight Control, Fig. 7 Simulink® simulation of helicopter pitch and roll responses before and after system “failure.” Note

that, although there have been significant reductions in stability augmentation gains and control inceptor sensitivities, tracking performance remains reasonably constant

It should be noted that in Hess (2016), the adaptive pilot model is not limited to one axis of control. Examples in which the pilot is controlling two axes, e.g., aircraft pitch and roll, are presented.

An Example of Adaptive Pilot Modeling

The following example deals with piloted control of a hovering helicopter. The helicopter dynamics and flight control system are taken from Hall and Bryson (1973). Two vehicle axes are being controlled by the pilot, pitch attitude (θ), and roll attitude (ϕ). Random-appearing sums of sinusoids provided commands to the pitch and roll axes (θ_c and ϕ_c). Of particular importance is

the fact that control response coupling was in evidence in the vehicle model, i.e. inputs to control pitch attitude also affected roll attitude and vice-versa. The vehicle “failures” were created by reducing the gain of the pitch and roll stability augmentation systems by a factor of 10 and reducing the sensitivity of the cockpit inceptors by a factor of 5. The failures were introduced at $t=50$ s in a 120 s simulation conducted using MATLAB Simulink®. Details can be found in Hess (2016).

Figure 7 shows the pitch and roll attitude responses before and after the failure with the dashed line representing the pitch and roll command (θ_c , ϕ_c) and the solid lines representing the corresponding pilot/vehicle responses. Figure 8 shows the adaptive pilot model gains K_p and K_r for each loop.

Adaptive Human Pilot Models for Aircraft Flight Control, Fig. 8

Adaptive pilot model gains in the pitch and roll attitude control loops. As might be expected, the sharp reduction in control and inceptor sensitivities in the failure is accommodated by the adaptive model by increases in K_p and K_r in each control axis. Of equal importance is the fact that crossover model characteristics were in evidence when the K_p and K_r assumed their final values, as they were at the initiation of the adaptive changes

Abstract

This entry deals with the kinematic self-coordination aspects to be managed by parts of underwater floating manipulators, whenever employed for sample collections at the seafloor.

Kinematic self-coordination is here intended as the autonomous ability exhibited by the system in closed loop specifying the most appropriate reference velocities for its main constitutive parts (i.e., the supporting vehicle and the arm) in order to execute the sample collection with respect to both safety and best operability conditions for the system while also guaranteeing the needed “execution agility” in performing the task, particularly useful in case of underwater repeated collections. To this end, the devising and employment of a unifying control framework capable of guaranteeing the above properties will be outlined.

Such a framework is however intended to only represent the so-called Kinematic Control Layer (KCL) overlaying a Dynamic Control Layer (DCL), where the overall system dynamic and hydrodynamic effects are suitably accounted for, to the benefit of closed loop tracking of the reference system velocities. Since the DCL design is carried out in a way which is substantially independent from the system mission(s), it will not constitute a specific topic of this entry, even if some orienting references about it will be provided.

At this entry’s end, as a follow-up of the resulting structural invariance of the devised KCL framework, future challenges addressing much wider and complex underwater applications will be foreseen, beyond the here-considered sample collection one.

Introduction

An automated system for underwater sampling is here intended to be an autonomous underwater floating manipulator (see Fig. 1) capable of collecting samples corresponding to an a priori assigned template. The snapshots of Fig. 1 outline the most recent realization of a system of this kind (completed in 2012 within the EU-funded project TRIDENT; Sanz et al. 2012) when in operation, which is characterized by a vehicle and an endowed 7-dof arm exhibiting comparable masses and inertia, thus resulting in potentially faster and more agile designs than the very few similar previous realizations.

Its general the operational mode consists in exploring an assigned area of the seafloor, while executing a collection each time a feature corresponding to the assigned template is recognized (by the vehicle endowed with a stereovision system) as a sample to be collected.

Thus the autonomous functionalities to be exhibited are the following (to be sequenced as they are listed on an event-driven basis): (1) explore an assigned seabed area while visually performing model-based sample recognitions, (2) suspend the exploration and grasping a recognized sample, (3) deposit the sample inside an endowed container, and (4) then restart exploring till the next recognized sample.

Functionalities (1) and (4), since they do not require the arm usage, naturally reenter within the topics of navigation, patrolling, visual mapping, etc., which are typical of traditional AUVs and consequently will not be discussed here. Only functionality (2) will be discussed, since it is most distinctive of the considered system (often termed as I-AUV, with “I” for “Intervention”) and because functionality (3) can be established along the same lines of (2) as a particular simpler case.

By then focusing on functionality (2), we must note how the sample grasping ultimate

Advanced Manipulation for Underwater Sampling, Fig. 1 Snapshots showing the underwater floating manipulator TRIDENT when autonomously picking an identified object

objective, which translates into a specific position/attitude to be reached by the end-effector, must however be achieved within the preliminary fulfillment of also other objectives, each one reflecting the need of guaranteeing the system operating within both its safety and best operability conditions. For instance, the arm's joint limits must be respected and the arm singular postures avoided. Moreover, since the sample position is estimated via the vehicle with a stereo camera, the sample must stay grossly centered inside its visual cone, since otherwise the visual feedback would be lost and the sample search would need to start again. Also, the sample must stay within suitable horizontal and vertical distance limits from the camera frame, in order for the vision algorithm to be well performing. And furthermore, in these conditions the vehicle should be maintained with an approximately horizontal attitude, for energy savings.

With the exception of the objective of making the end-effector position/attitude reaching the grasping position, which is clearly an equality condition, its related safety/enabling objectives are instead represented by a set of inequality conditions (involving various system variables) whose achievement (accordingly with their safety/enabling role) must therefore deserve the highest priority.

System motions guaranteeing such prioritized objective achievements should moreover allow for a concurrent management of them (i.e., avoiding a sequential motion management whenever possible), which means requiring each objective progressing toward its achievement, by at each time instant only exploiting the residual system mobility allowed by the current progresses of its higher priority objectives. Since the available system mobility will progressively increase during time, accordingly with the progressive achievement of all inequality objectives, this will guarantee the grasping objective to be also completed by eventually progressing within adequate system safety and best operability conditions. In this way the system will also exhibit the necessary “agility” in executing its maneuvers, in a way faster than in case they were executed on a sequential motion basis.

The devising of an effective way to incorporate all the inequality and equality objectives within a uniform and computationally efficient task-priority-based algorithmic framework for underwater floating manipulators has been the result of the developments outlined in the next section.

The developed framework however solely represents the so-called Kinematic Control Layer (KCL) of the overall control architecture, that is, the one in charge of closed-loop real-time

control generating the system velocity vector y as a reference signal, to be in turn concurrently tracked, via the action of the arm joint torques and vehicle thrusters, by an adequate underlying Dynamic Control Layer (DCL), where the overall dynamic and hydrodynamic effects are kept into account to the benefit of such velocity tracking. Since the DCL can actually be designed in a way substantially independent from the system mission(s), it will not constitute a specific topic of this entry. Its detailed dynamic-hydrodynamic model-based structuring, also including a stability analysis, can be found in Casalino (2011), together with a more detailed description of the upper-lying KCL, while more general references on underwater dynamic control aspects can be found, for instance, in Antonelli (2006).

Task-Priority-Based Control of Floating Manipulators

The above-outlined typical set of objectives (of inequality and/or equality types) to be achieved within a sampling mission are here formalized. Then some helpful generalizing definitions are given, prior to presenting the related unifying task-priority-based algorithmic framework to be used.

Inequality and Equality Objectives

One of the objectives, of inequality type, related to both arm safety and its operability is that of maintaining each joint within corresponding minimum and maximum limits, that is,

$$q_{lm} < q_i < q_{im}; \quad i = 1, 2, \dots, 7$$

Moreover, in order to have the arm operating with dexterity, its manipulability measure (Yoshikawa 1985; Nakamura 1991) must ultimately stay above a minimum threshold value, thus also requiring the achievement of the inequality type objective

$$\mu > \mu_m$$

While the above objectives arise from inherently scalar variables, other objectives instead arise as

conditions to be achieved within the Cartesian space, where each one of them can be conveniently expressed in terms of the modulus associated to a corresponding Cartesian vector variable.

To be more specific, let us, for instance, refer to the need of avoiding the occlusions between the sample and the stereo camera, which might occasionally occur due to the arm link motions. Then such need can be, for instance, translated into the ultimate achievement of the following set of inequalities, for suitable chosen values of the boundaries

$$\|l\| > l_m; \quad \|\tau\| > \tau_m; \quad \|\eta\| < \eta_M$$

where l is the vector lying on the vehicle x-y plane, joining the arm elbow with the line parallel to the vehicle z-axis and passing through camera frame origin, as sketched in Fig. 2a. Moreover η is the misalignment vector formed by vector τ also lying on the vehicle x-y plane, joining the lines parallel to the vehicle z-axis and, respectively, passing through the elbow and the end-effector origin.

As for the vehicle, it must keep the object of interest grossly centered in the camera frame (see Fig. 2b), thus meaning that the modulus of the orientation error ξ , formed by the unit vector n_p of vector p from the sample to the camera frame and the unit vector k_c of the z-axis of the camera frame itself, must ultimately satisfy the inequality

$$\|\xi\| < \xi_M$$

Furthermore, the camera must also be closer than a given horizontal distance d_M to the vertical line passing through the sample, and it must lie between a maximum and minimum height with respect to the sample itself, thus implying the achievement of the following inequalities (Fig. 2c, d):

$$\|d\| < d_M; \quad h_m < \|h\| < h_M$$

Also since the vehicle should exhibit an almost horizontal attitude, this further requires the achievement of the following additional inequality:

$$\|\phi\| < \phi_M$$

Advanced Manipulation for Underwater Sampling, Fig. 2 Vectors allowing for the definition of some inequality objectives in the Cartesian space: (a) camera occlusion, (b) camera centering, (c) camera distance, (d) camera height

with ϕ the misalignment vector formed by the absolute vertical unit vector k_o with the vehicle z-axis one k_v .

And finally the end-effector must eventually reach the sample, for then picking it. Thus the following, now of equality type, objectives must also be ultimately achieved, where r is the position error and θ the orientation one of the end-effector frame with respect to the sample frame

$$\|r\| = 0; \quad \|\vartheta\| = 0$$

As already repeatedly remarked, the achievement of the above inequality objectives (since related to the system safety and/or its best operability)

must globally deserve a priority higher than the last equality.

Basic Definitions

The following definitions only regard a generic vector $s \in R^3$ characterizing a corresponding generic objective defined in the Cartesian space (for instance, with the exclusion of the joint and manipulability limits, all the other above-reported objectives). In this case the vector is termed to be the error vector of the objective, and it is assumed measured with components on the vehicle frame. Then its modulus

$$\sigma \doteq \|s\|$$

is termed to be the error, while its unit vector

$$n \doteq s/\sigma; \quad \sigma \neq 0$$

is accordingly denoted as the unit error vector. Then the following differential Jacobian relationship can always be evaluated for each of them:

$$\dot{s} = Hy$$

where $y \in R^N$ ($N = (7 + 6)$ for the system of Fig. 1) is the stacked vector composed of the joint velocity vector $\dot{q} \in R^7$, plus the stacked vector $v \in R^6$ of the absolute vehicle velocities (linear and angular) with components on the vehicle frame and with $\dot{s}$ clearly representing the time derivative of vector s itself, as seen from the vehicle frame and with components on it (see Casalino (2011) for details on the real-time evaluation of Jacobian matrices H).

Obviously, for the time derivative $\dot{\sigma}$ of the error, also the following differential relationship holds

$$\dot{\sigma} = n^T Hy$$

Further, to each error variable σ , a so-called error reference rate is real time assigned of the form

$$\dot{\sigma} = -\gamma(\sigma - \sigma^o)\alpha(\sigma)$$

where for equality objectives σ^o is the target value and $\alpha(\sigma) \equiv 1$, while for inequality ones, σ^o is the threshold value and $\alpha(\sigma)$ is a left-cutting or right-cutting (in correspondence of σ^o) smooth sigmoidal activation function, depending on whether the objective is to force σ to be below or above σ^o , respectively.

In case $\dot{\sigma}$ could be exactly assigned to its corresponding error rate $\dot{\sigma}$, it would consequently smoothly drive σ toward the achievement of its associated objective. Note however that for inequality objectives, it would necessarily impose $\dot{\sigma} = 0$ in correspondence of a point located inside the interval of validity of the inequality objective itself, while instead such an error rate zeroing effect should be relaxed, for allowing the helpful subsequent system mobility increase, which allows for further progress toward other

lower priority control objectives. Such a relaxation aspect will be dealt with soon.

Furthermore, in correspondence of a reference error rate $\dot{\sigma}$, the so-called reference error vector rate can also be defined as

$$\dot{s} \doteq n\dot{\sigma}$$

that for equality objectives requiring the zeroing of their error σ simply becomes

$$\dot{s} \doteq -\gamma s$$

whose evaluation, since not requiring its unit vector n , will be useful for managing equality objectives.

Finally note that for each objective not defined in the Cartesian space (like, for instance, the above joint limits and manipulability), the corresponding scalar error variable, its rate, and its reference error rate can instead be managed directly, since obviously they do not require any preliminary scalar reduction process.

Managing the Higher Priority Inequality Objectives

A prioritized list of the various scalar inequality objectives, to be concurrently progressively achieved, is suitably established in a descending priority order.

Then, by starting to consider the highest priority one, we have that the linear manifold of the system velocity vector y (i.e., the arm joints velocity vector $\dot{q}$ stacked with vector v of the vehicle linear and angular velocities), capable of driving toward its achievement, results at each time instant as the set of solution of the following minimization problem with scalar argument, with row vector $G_1 \doteq \alpha_1 n_1^T H_1$ and scalar α_1 the same activation function embedded within the reference error rate $\dot{\sigma}_1$

$$S_1 \doteq \left\{ \underset{y}{\operatorname{argmin}} \left\| \dot{\sigma}_1 - G_1 y \right\|^2 \right\} \Leftrightarrow$$

$$y = G_1^\# \dot{\sigma}_1 + (I - G_1^\# G_1) z_1 \doteq \rho_1 + Q_1 z_1; \quad \forall z_1$$

(1)

The above minimization, whose solution manifold appears at the right (also expressed in a concise notation with an obvious correspondence of terms) parameterized by the arbitrary vector z_1 , has to be assumed executed without extracting the common factor α_1 , that is, by evaluating the pseudo-inverse matrix $G_1^\#$ via the regularized form

$$G_1^\# = \left(\alpha_1^2 n_1^T H_1 H_1^T n_1 + p_1 \right)^{-1} \alpha_1 H_1^T n_1$$

with p_1 , a suitably chosen bell-shaped, finite support and centered on zero, regularizing function of the norm of row vector G_1 .

In the above solution manifold, when $\alpha_1 = 1$ (i.e., when the first inequality is still far to be achieved), the second arbitrary term $Q_1 z_1$ is orthogonal to the first, thus having no influence on the generated $\dot{\sigma}_1 = \dot{\bar{\sigma}}_1$ and consequently suitable to be used for also progressing toward the achievement of other lower priority objectives, without perturbing the current progressive achievement of the first one. Note however that, since in this condition the span of the second term results one dimension less than the whole system velocity space $y \in R^N$, this implies that the lower priority objectives can be progressed by only acting within a one-dimension reduced system velocity subspace.

When $\alpha_1 = 0$ (i.e., when the first inequality is achieved) since $G_1^\# = 0$ (as granted by the regularization) and consequently $y = z_1$, the lower priority objectives can instead be progressed by now exploiting the whole system velocity space.

When instead α_1 is within its transition zone $0 < \alpha_1 < 1$ (i.e., when the first inequality is near to be achieved), since the two terms of the solution manifold now become only approximately orthogonal, this can make the usage of the second term for managing lower priority tasks, possibly counteracting the first, currently acting in favor of the highest priority one, but in any case without any possibility of making the primary error variable σ_1 getting out of its enlarged boundaries (i.e., the ones inclusive of the transition zone), thus meaning that once the primary variable σ_1

has entered within such larger boundaries, it will definitely never get out of them.

With the above considerations in mind, managing the remaining priority-descending sequence of inequality objectives can then be done by applying the same philosophy to each of them and within the mobility space left free by its preceding ones, that is, as the result of the following sequence of nested minimization problems:

$$S_i \doteq \left\{ \underset{y \in S_{i-1}}{\operatorname{argmin}} \left\| \dot{\bar{\sigma}}_i - G_i y \right\|^2 \right\}; \quad i = 1, 2, \dots, k$$

with $G_i \doteq \alpha_i n_i^T H_i$ and with k indexing the lowest priority inequality objective and where the highest priority objective has been also included for the sake of completeness (upon letting $S_0 = R^N$). In this way the procedure guarantees the concurrent prioritized convergence (actually occurring as a sort of “domino effect” scattering along the prioritized objective list) toward the ultimate fulfillment of all inequality objectives, each one within its enlarged bounds at worse and with no possibility of getting out of them, once reached.

Further, a simple algebra allows translating the above sequence of k nested minimizations into the following algorithmic structure, with initialization $\rho_0 = 0$; $Q_0 = I$ (see Casalino et al. 2012a, b for more details):

$$\hat{G}_1 \doteq G_1 Q_i$$

$$T_i = \left(I - Q_{i-1} G_i^\# G_i \right)$$

$$\rho_i = T_i \rho_{i-1} + Q_{i-1} G_i^\# \dot{\bar{\sigma}}_i$$

$$Q_i = Q_{i-1} \left(I - G_i^\# G_i \right)$$

ending with the last k -th iteration with the solution manifold

$$y = \rho_k + Q_k z_k; \quad \forall z_k$$

where the residual arbitrariness space $Q_k z_k$ has to be then used for managing the remaining equality objectives, as hereafter indicated.

Managing the Lower Priority Equality Objectives and Subsystem Motion Priorities

For managing the lower priority equality objectives when these require the zeroing of their associated error σ_i (as, for instance, for the end-effector sample reaching task), the following sequence of nested minimization problems has to be instead considered (with initialization ρ_k ; Q_k):

$$S_i \doteq \left\{ \operatorname{argmin}_{y \in S_{i-1}} \|\dot{\hat{s}}_i - H_i y\|^2 \right\}; \quad i = (k+1), \dots, m$$

with m indexing the last priority equality objective and where the whole reference error vector rates $\dot{\hat{s}}_i$ and associated whole error vectors $\hat{s}_i$ have now to be used, since for $\alpha_i \equiv 1$ (as it is for any equality objective) the otherwise needed evaluation of unit vectors n_i (which become ill defined for the relevant error σ_i approaching zero) would most probably provoke unwanted chattering phenomena around $\sigma_i = 0$, while instead the above avoids such risk (since $\dot{\hat{s}}_i$ and $\hat{s}_i$ can be evaluated without requiring n_i), even if at the cost of requiring, for each equality objective, three degrees of mobility instead of a sole one, as it instead is for each inequality objectives. However, note how the algorithmic translation of the above procedure remains structurally the same as the one for the inequality objectives (obviously with the substitutions $\dot{\hat{s}}_i \rightarrow \dot{\hat{\sigma}}_i$, $H_i \rightarrow G_i$, and with initialization ρ_k , Q_k), thus ending in correspondence of the m -th last equality objective with the solution manifold

$$y = \rho_m + Q_m z_m; \quad \forall z_m$$

where the still possibly existing residual arbitrariness space $Q_m z_m$ can be further used for assigning motion priorities between the arm and the vehicle, for instance, via the following additional least-priority ending task

$$y = \operatorname{argmin}_{y \in S_m} \|v\|^2 = \rho_{m+1}$$

whose solution ρ_{m+1} (with no more arbitrariness required) finally assures (while respecting all previous priorities) a motion minimality of the vehicle, thus implicitly assigning to the arm a greater mobility, which in turn allows the exploitation of its generally higher motion precision, especially during the ultimate convergence toward the final grasping.

Implementations

The recently realized TRIDENT system of Fig. 1, embedding the above introduced task-priority-based control architecture, has been operating at sea in 2012 (Port Soller Harbor, Mallorca, Spain). A detailed presentation of the preliminary performed simulations, then followed by pool experiments, and finally followed by field trials executed within a true underwater sea environment can be found in Simetti et al. (2013). The related EU-funded TRIDENT project (Sanz et al. 2012) is the first one where agile manipulation could be effectively achieved by part of an underwater floating manipulator, not only as the consequence of the comparable masses and inertia exhibited by the vehicle and arm, but mainly due to the adopted unified task-priority-based control framework. Capabilities for autonomous underwater floating manipulation were however already achieved for the first time in 2009 at the University of Hawaii, within the SAUVIM project (Yuh et al. 1998; Marani et al. 2009, 2014) even if without effective agility (the related system was in fact a 6-t vehicle endowed with a less than 35 kg arm).

Future Directions

The presented task-priority-based KCL structure is invariant with the addition, deletion, and substitution (even on-the-fly) of the various objectives, as well as invariant to changes in their priority ordering, thus constituting an invariant core potentially capable of supporting intervention tasks beyond the sole sample collection ones. On this basis, more complex systems and operational

Advanced Manipulation for Underwater Sampling, Fig. 3 A sketch of the foreseen roadmap for future development of marine intervention robotics

cases, such as, for instance, multi-arm systems and/or even cooperating ones, can be foreseen to be developed along the lines established by the roadmap of Fig. 3 (with case 0 the current development state).

The future availability of agile floating single-arm or multi-arm manipulators, also implementing cooperative interventions in force of a unified control and coordination structure (to this aim purposely extended), might in fact pave the way toward the realization of underwater hard-work robotized places, where different intervention agents might individually or cooperatively perform different object manipulation and transportation activities, also including assembly ones, thus far beyond the here considered case of sample collection. Such scenarios deserve the attention not only of the science community when needing to execute underwater works (excavation, coring, instrument handling, etc., other than sample collection) at increasing depths but obviously also those of the offshore industry.

Moreover, by exploiting the current and future developments on underwater exploration and survey mission performed by normal AUVs (i.e., nonmanipulative), a possible work scenario might also include the presence of these last, for accomplishing different service activities supporting the intervention ones, for instance, relays with the surface, then informative activities

(for instance, the delivery of the area model built during a previous survey phase or the delivery of the intervention mission, both downloaded when in surface and then transferred to the intervention agents upon docking), or even when hovering on the work area (for instance, close to a well-recognized feature) behaving as a local reference system for the self-localization of the operative agents via twin USBL devices.

Air Traffic Management Modernization: Promise and Challenges

Christine Haissig

Honeywell International Inc., Minneapolis, MN, USA

Abstract

This entry provides a broad overview of how air traffic for commercial air travel is scheduled and managed throughout the world. The major causes of delays and congestion are described, which include tight scheduling, safety restrictions, infrastructure limitations, and major disturbances. The technical and financial challenges to air traffic management are outlined, along with some of the promising developments for future modernization.

Introduction: How Does Air Traffic Management Work?

This entry focuses on air traffic management for commercial air travel, the passenger- and cargo-carrying operations with which most of us are familiar. This is the air travel with a pressing need for modernization to address current and future congestion. Passenger and cargo traffic is projected to double over the next 20 years, with growth rates of 3–4 % annually in developed markets such as the USA and Europe and growth rates of 6 % and more in developing markets such as Asia Pacific and the Middle East.

In most of the world, air travel is a distributed, market-driven system. Airlines schedule flights based on when people want to fly and when it is optimal to transport cargo. Most passenger flights are scheduled during the day; most package carrier flights are overnight. Some airports limit how many flights can be scheduled by having a slot system, others do not. This decentralized schedule of flights to and from airports around the world is controlled by a network of air navigation service providers (ANSPs) staffed with air traffic controllers, who ensure that aircraft are separated safely.

The International Civil Aviation Organization (ICAO) has divided the world's airspace into flight information regions. Each region has a country that controls the airspace, and the ANSP for each country can be a government department, state-owned company, or private organization. For example, in the United States, the ANSP is the Federal Aviation Administration (FAA), which is a government department. The Canadian

ANSP is NAV CANADA, which is a private company.

Each country is different in terms of the services provided by the ANSP, how the ANSP operates, and the tools available to the controllers. In the USA and Europe, the airspace is divided into sectors and areas around airports. An air traffic control center is responsible for traffic flow within its sector and rules and procedures are in place to cover transfer of control between sectors. The areas around busy airports are usually handled by a terminal radar approach control. The air traffic control tower personnel handle departing aircraft, landing aircraft, and the movement of aircraft on the airport surface.

Air traffic controllers in developed air travel markets like the USA and Europe have tools that help them with the business of controlling and separating aircraft. Tower controllers operating at airports can see aircraft directly through windows or on computer screens through surveillance technology such as radar and Automatic Dependent Surveillance-Broadcast (ADS-B). Tower controllers may have additional tools to help detect and prevent potential collisions on the airport surface. En route controllers can see aircraft on computer screens and may have additional tools to help detect potential losses of separation between aircraft. Controllers can communicate with aircraft via radio and some have datalink communication available such as Controller-Pilot Datalink Communications (CPDLC).

Flight crews have tools to help with navigating and flying the airplane. Autopilots and autothrottles off-load the pilot from having to continuously control the aircraft; instead the pilot can specify the speed, altitude, and heading and the autopilot and autothrottle will maintain those commands. Flight management systems (FMS) assist in flight planning in addition to providing lateral and vertical control of the airplane. Many aircraft have special safety systems such as the Traffic Alert and Collision Avoidance System, which alerts the flight crew to potential collisions with other airborne aircraft, and the Terrain Avoidance Warning Systems (TAWS), which alert the flight crew to potential flight into terrain.

Causes of Congestion and Delays

Congestion and delays are caused by multiple reasons. These include tight scheduling, safety limitations on how quickly aircraft can take off and land and how closely they can fly, infrastructure limitations such as the number of runways at an airport and the airway structure, and disturbances such as weather and unscheduled maintenance.

Tight Scheduling

Tight scheduling is a major contributor to congestion and delays. The hub and spoke system that many major airlines operate with to minimize connection times means that aircraft arrive and depart in multiple banks during the day. During the arrival and departure banks, airports are very busy. As mentioned previously, passengers have preferred times to travel, which also increase demand at certain times. At airports that do not limit flight schedules by using slot scheduling, the number of flights scheduled can actually exceed the departure and arrival capacity of the airport even in best-case conditions. One of the reasons that airlines are asked to report on-time statistics is to make the published airline schedules more reflective of the average time from departure to arrival, not the best-case time.

Aircraft themselves are also tightly scheduled. Aircraft are an expensive capital asset. Since customers are very sensitive to ticket prices, airlines need to have their aircraft flying as many hours as possible per day. Airlines also limit the number of spare aircraft and flight crews available to fill in when operations are disrupted to control costs.

Safety Restrictions

Safety restrictions contribute to congestion. There is a limit to how quickly aircraft can take off from and land on a runway. Sometimes runways are used for both departing and arriving aircraft; at other times a runway may be used for departures only or arrivals only. Either way, the rule that controllers follow for safety is that only one aircraft can occupy the runway at one time. Thus, a landing aircraft must turn off of the runway before another aircraft can take off

or land. This limitation and other limitations like the ability of controllers to manage the arrival and departure aircraft propagate backwards from the airport. Aircraft need to be spaced in an orderly flow and separated no closer than what can be supported by airport arrival rates. The backward propagation can go all the way to the departure airports and cause aircraft to be held on the ground as a means to regulate the traffic flow into a congested airport or through a congested air traffic sector.

There is a limit on how close aircraft can fly. Aircraft produce a wake that can be dangerous for other aircraft that are following too closely behind. Pilots are aware of this limitation and space safely when doing visual separation. Rules that controllers apply for separation take into account wake turbulence limitations, surveillance limitations, and limitations on how well aircraft can navigate and conform to the required speed, altitude, and heading.

The human is a safety limitation. Controllers and pilots are human. Being human, they have excellent reasoning capability. However, they are limited as to the number of tasks they can perform and are subject to fatigue. The rules and procedures in place to manage and fly aircraft take into account human limitations.

Infrastructure Limitations

Infrastructure limitations contribute to congestion and delays. Airport capacity is one infrastructure limitation. The number of runways combined with the available aircraft gates and capacity to process passengers through the terminal limit the airport capacity.

The airspace itself is a limitation. The airspace where controllers provide separation services is divided into an orderly structure of airways. The airways are like one-way, one-lane roads in the sky. They are stacked at different altitudes, which are usually separated by either 1,000 ft. or 2,000 ft. The width of the airways depends on how well aircraft can navigate. In the US domestic airspace where there are regular navigation aids and direct surveillance of aircraft, the airways have a plus or minus 4 NM width. Over the ocean, airways may need to be separated

laterally by as much as 120 NM since there are fewer navigation aids and aircraft are not under direct control but separated procedurally. The limited number of airways that the airspace can support limits available capacity.

The airways themselves have capacity limitations just as traditional roads do. There are special challenges for airways since aircraft need a minimum separation distance, aircraft cannot slow down to a stop, and airways do not allow passing. So, although it may look like there is a lot of space in which aircraft can fly, there are actually a limited number of routes between a city pair or over oceanic airspace.

The radio that is used for pilots and controllers to communicate is another infrastructure limitation. At busy airports, there is significant radio congestion and pilots may need to wait to get an instruction or response from a controller.

Disturbances

Weather is a significant disturbance in air traffic management. Weather acts negatively in many ways. Wet or icy pavement affects the braking ability of aircraft so they cannot vacate a runway as quickly as in dry conditions. Low cloud ceilings mean that all approaches must be instrument approaches rather than visual approaches, which also reduces runway arrival rates. Snow must be cleared from runways, closing them for some period of time. High winds can mean that certain approaches cannot be used because they are not safe. In extreme weather, an airport may need to close. Weather can block certain airways from use, requiring rerouting of aircraft. Rerouting increases demand on nearby airways, which may or may not have the required additional capacity, so the rerouting cascades on both sides of the weather.

Why Is Air Traffic Management Modernization So Hard?

Air traffic management modernization is difficult for financial and technical reasons. The air traffic management system operates around the clock. It cannot be taken down for a significant period of

time without a major effect on commerce and the economy.

Financing is a significant challenge for air traffic management modernization. Governments worldwide are facing budgetary challenges and improvements to air travel are one of many competing financial interests. Local airport authorities have similar challenges in raising money for airport improvements. Airlines have competitive limitations on how much ticket prices can rise and therefore need to see a payback on investment in aircraft upgrades that can be as short as 2 years.

Another financial challenge is that the entity that needs to pay for the majority of an improvement may not be the entity that gets the majority of the benefit, at least near term. One example of this is the installation of ADS-B transmitters on aircraft. Buying and installing an ADS-B transmitter costs the aircraft owner money. It benefits the ANSPs, who can receive the transmissions and have them augment or replace expensive radar surveillance, but only if a large number of aircraft are equipped. Eventually the ANSP benefit will be seen by the aircraft operator through lower operating costs but it takes time. This is one reason that ADS-B transmitter equipage was mandated in the USA, Europe, and other parts of the world rather than letting market forces drive equipage.

All entities, whether governmental or private, need some sort of business case to justify investment, where it can be shown that the benefit of the improvement outweighs the cost. The same system complexity that makes congestion and delays in one region propagate throughout the system makes it a challenge to accurately estimate benefits. It is complicated to understand if an improvement in one part of the system will really help or just shift where the congestion points are. Decisions need to be made on what improvements are the best to invest in. For government entities, societal benefits can be as important as financial payback, and someone needs to decide whose interests are more important. For example, the people living around an airport might want longer arrival paths at night to minimize noise while air travelers and the airline want the airline to fly the most direct route into an airport. A combination

of subject matter expertise and simulation can provide a starting point to estimate benefit, but often only operational deployment will provide realistic estimates.

It is a long process to develop new technologies and operational procedures even when the benefit is clear and financing is available. The typical development steps include describing the operational concept; developing new controllers procedures, pilot procedures, or phraseology if needed; performing a safety and performance analysis to determine high level requirements; performing simulations that at some point may include controllers or pilots; designing and building equipment that can include software, hardware, or both; and field testing or flight testing the new equipment. Typically, new ground tools are field tested in a shadow mode, where controllers can use the tool in a mock situation driven by real data before the tool is made fully operational. Flight testing is performed on aircraft that are flying with experimental certificates so that equipment can be tested and demonstrated prior to formal certification.

Avionics need to be certified before operational use to meet the rules established to ensure that a high safety standard is applied to air travel. To support certification, standards are developed. Frequently the standards are developed through international cooperation and through consensus decision-making that includes many different organizations such as ANSPs, airlines, aircraft manufacturers, avionics suppliers, pilot associations, controller associations, and more. This is a slow process but an important one, since it reduces development risk for avionics suppliers and helps ensure that equipment can be used worldwide.

Once new avionics or ground tools are available, it takes time for them to be deployed. For example, aircraft fleets are upgraded as aircraft come in for major maintenance rather than pulling them out of scheduled service. Flight crews need to be trained on new equipment before it can be used, and training takes time. Ground tools are typically deployed site by site, and the controllers also require training on new equipment and new procedures.

Promise for the Future

Despite the challenges and complexity of air traffic management, there is a path forward for significant improvement in both developed and developing air travel markets. Developing air travel markets in countries like China and India can improve air traffic management using procedures, tools, and technology that is already used in developed markets such as the USA and Europe. Emerging markets like China are willing to make significant investments in improving air traffic management by building new airports, expanding existing airports, changing controller procedures, and investing in controller tools. In developed markets, new procedures, tools, and technologies will need to be implemented. In some regions, mandates and financial incentives may play a part in enabling infrastructure and equipment changes that are not driven by the marketplace.

The USA and Europe are both supporting significant research, development, and implementation programs to support air traffic management modernization. In the USA, the FAA has a program known as NextGen, the Next Generation Air Transportation System. In Europe, the European Commission oversees a program known as SESAR, the Single European Sky Air Traffic Management Research, which is a joint effort between the European Union, EUROCONTROL, and industry partners. Both programs have substantial support and financing. Each program has organized its efforts differently but there are many similarities in the operational objectives and improvements being developed.

Airport capacity problems are being addressed in multiple ways. Controllers are being provided with advanced surface movement guidance and control systems that combine radar surveillance, ADS-B surveillance, and sensors installed at the airport with valued-added tools to assist with traffic control and alert controllers to potential collisions. Datalink communications between controllers and pilots will reduce radio-frequency congestion, reduce communication errors, and enable more complex communication. The USA and Europe have plans to develop a modernized

datalink communication infrastructure between controllers and pilots that would include information like departure clearances and the taxiway route clearance. Aircraft on arrival to an airport will be controlled more precisely by equipping aircraft with capabilities such as the ability to fly to a required time of arrival and the ability to space with respect to another aircraft.

Domestic airspace congestion is being addressed in Europe by moving towards a single European sky where the ANSPs for the individual nations coordinate activities and airspace is structured not as 27 national regions but operated as larger blocks. Similar efforts are undergoing in the USA to improve the cooperation and coordination between the individual airspace sectors. In some countries, large blocks of airspace are reserved for special use by the military. In those countries, efforts are in place to have dynamic special use airspace that is reserved on an as-needed basis but otherwise available for civil use.

Oceanic airspace congestion is being addressed by leveraging the improved navigation performance of aircraft. Some route structures are available only to aircraft that can flight to a required navigation performance. These route structures have less required lateral separation, and thus more routes can be flown in the same airspace. Pilot tools that leverage ADS-B are allowing aircraft to make flight level changes with reduced separation and in the future are expected to allow pilots to do additional maneuvering that is restricted today, such as passing slower aircraft.

Weather cannot be controlled but efforts are underway to do better prediction and provide more accurate and timely information to pilots, controllers, and aircraft dispatchers at airlines. On-board radars that pilots use to divert around weather are adding more sophisticated processing algorithms to better differentiate hazardous weather. Future flight management systems will have the capability to include additional weather information. Datalinks between the air and the ground or between aircraft may be updated to include information from the on-board radar systems, allowing aircraft to act as local weather

sensors. Improved weather information for pilots, controllers, and dispatchers improves flight planning and minimizes the necessary size of deviations around hazardous weather while retaining safety.

Weather is also addressed by providing aircraft and airports with equipment to improve airport access in reduced visibility. Ground-based augmentation systems installed at airports provide aircraft with the capability to do precision-based navigation for approaches to airports with low weather ceilings. Other technologies like enhanced vision and synthetic vision, which can be part of a combined vision system, provide the capability to land in poor visibility.

Summary

Air traffic management is a complex and interesting problem. The expected increase in air travel worldwide is driving a need for improvements to the existing system so that more passengers can be handled while at the same time reducing congestion and delays. Significant research and development efforts are underway worldwide to develop safe and effective solutions that include controller tools, pilot tools, aircraft avionics, infrastructure improvements, and new procedures. Despite the technical and financial challenges, many promising technologies and new procedures will be implemented in the near, mid-, and far term to support air traffic management modernization worldwide.

Aircraft Flight Control

Dale Enns

Honeywell International Inc., Minneapolis, MN, USA

Abstract

Aircraft flight control is concerned with using the control surfaces to change aerodynamic moments, to change attitude angles of the aircraft relative to the air flow, and ultimately change the aerodynamic forces to allow the aircraft to achieve the desired maneuver or steady condition. Control laws create the commanded control surface positions based on pilot and sensor inputs. Traditional control laws employ proportional and integral compensation with scheduled gains, limiting elements, and cross feeds between coupled feedback loops. Dynamic inversion is an approach to develop control laws that systematically addresses the equivalent of gain schedules and the multivariable cross feeds, can incorporate constrained optimization for the limiting elements, and maintains the use of proportional and integral compensation to achieve the benefits of feedback.

Introduction

Flying is made possible by flight control and this applies to birds and the Wright Flyer, as well as modern flight vehicles. In addition to balancing lift and weight forces, successful flight also requires a balance of moments or torques about the mass center. Control is a means to adjust these moments to stay in equilibrium and to perform maneuvers. While birds use their feathers and

the Wright Flyer warped its wings, modern flight vehicles utilize hinged control surfaces to adjust the moments. The control action can be open or closed loop, where closed loop refers to a feedback loop consisting of sensors, computer, and actuation. A direct connection between the cockpit pilot controls and the control surfaces without a feedback loop is open loop control. The computer in the feedback loop implements a control law (computer program). The development of the control law is discussed in this entry.

Although the following discussion is applicable to a wide range of flight vehicles including gliders, unmanned aerial vehicles, lifting bodies, missiles, rockets, helicopters, and satellites, the focus of this entry will be on fixed wing commercial and military aircraft with human pilots.

Flight

Aircraft are maneuvered by changing the forces acting on the mass center, e.g., a steady level turn requires a steady force towards the direction of turn. The force is the aerodynamic lift force (L) and it is banked or rotated into the direction of the turn. The direction can be adjusted with the bank angle (μ) and for a given airspeed (V) and air density (ρ), the magnitude of the force

can be adjusted with the angle-of-attack (α). This is called bank-to-turn. Aircraft, e.g., missiles, can also skid-to-turn where the aerodynamic side force (Y) is adjusted with the sideslip angle (β) but this entry will focus on bank-to-turn.

Equations of motion (Stevens and Lewis 1992; Enns et al. 1996) can be used to relate the time rates of change of μ , α , and β to roll (p), pitch (q), and yaw (r) rate. See Fig. 4. Approximate relations (for near steady level flight with no wind) are

$$\dot{\mu} = p$$

$$\dot{\alpha} = q + \frac{L - mg}{mV}$$

$$\dot{\beta} = -r + \frac{Y}{mV}$$

where m is the aircraft mass, and g is the gravitational acceleration. In straight and level flight conditions $L = mg$ and $Y = 0$ so we think of these equations as kinematic equations where the rates of change of the angles μ , α , and β are the angular velocities p , q , and r .

Three moments called roll, pitch, and yaw for angular motion to move the right wing up or down, nose up or down, and nose right or left, respectively create the angular accelerations to

Aircraft Flight Control,
Fig. 1 Flight control
variables

change p , q , and r , respectively. The equations are Newton's 2nd law for rotational motion. The moments (about the mass center) are dominated by aerodynamic contributions and depend on ρ , V , α , β , p , q , r , and the control surfaces. The control surfaces are aileron (δ_a), elevator (δ_e), and rudder (δ_r) and are arranged to contribute primarily roll, pitch, and yaw moments respectively.

The control surfaces (δ_a , δ_e , δ_r) contribute to angular accelerations which are integrated to obtain the angular rates (p , q , r). The integral of angular rates contributes to the attitude angles (μ , α , β). The direction and magnitude of aerodynamic forces can be adjusted with the attitude angles. The forces create the maneuvers or steady conditions for operation of the aircraft.

Pure Roll Axis Example

Consider just the roll motion. The differential equation (Newton's 2nd law for the roll degree-of-freedom) for this dynamical system is

$$\dot{p} = L_p p + L_{\delta_a} \delta_a$$

where L_p is the stability derivative and L_{δ_a} is the control derivative both of which can be regarded as constants for a given airspeed and air density.

Pitch Axis or Short Period Example

Consider just the pitch and heave motion. The differential equations (Newton's 2nd law for the pitch and heave degrees-of-freedom) for this dynamical system are

$$\dot{q} = M_\alpha \alpha + M_q q + M_{\delta_e} \delta_e$$

$$\dot{\alpha} = Z_\alpha \alpha + q + Z_{\delta_e} \delta_e$$

where M_α , M_q , Z_α are stability derivatives, and M_{δ_e} is the control derivative, all of which can be regarded as constants for a given airspeed and air density.

Although $Z_\alpha < 0$ and $M_q < 0$ are stabilizing, $M_\alpha > 0$ makes the short period motion inherently unstable. In fact, the short period motion of the Wright Flyer was unstable. Some modern aircraft are also unstable.

Lateral-Directional Axes Example

Consider just the roll, yaw, and side motion with four state variables (μ , p , r , β) and two inputs (δ_a , δ_r). We will use the standard state space equations with matrices A , B , C for this example.

The short period equations apply for yaw and side motion (or dutch roll motion) with appropriate replacements, e.g., q with r , α with $-\beta$, M with N . We add the term $V^{-1}g\mu$ to the $\dot{\beta}$ equation. We include the kinematic equation $\dot{\mu} = p$ and add the term $L_\beta \beta$ to the $\dot{p}$ equation. The dutch roll, like the short period, can be unstable if $N_\beta < 0$, e.g., airplanes without a vertical tail.

There is coupling between the motions associated with stability derivatives L_r , L_β , N_p and control derivatives L_{δ_r} and N_{δ_a} . This is a fourth order multivariable coupled system where δ_a , δ_r are the inputs and we can consider (p , r) or (μ , β) as the outputs.

Control

The control objectives are to provide stability, disturbance rejection, desensitization, and satisfactory steady state and transient response to commands. Specifications and guidelines for these objectives are assessed quantitatively with frequency, time, and covariance analyses and simulations.

Integrator with P + I Control

The system to be controlled is the integrator for y in Fig. 2 and the output of the integrator (y) is the controlled variable. The proportional gain ($K_b > 0$) is a frequency and sets the bandwidth or crossover frequency of the feedback loop. The value of K_b will be between 1 and 10 rad/s in most aircraft applications. Integral action can be included with the gain, $f_i > 0$ with a value between 0 and 1.5 in most applications. The value of the command gain, $f_c > 0$, is set to achieve a desired closed loop response from the command y_c to the output y . Values of $f_i = 0.25$ and $f_c = 0.5$ are typical. In realistic applications, there is a limit that applies at the input to the integrator. In these cases, we are obligated to include an anti-integral windup gain, $f_a > 0$ (typical value of 2)

Aircraft Flight Control, Fig. 2 Closed loop feedback system and desired dynamics

to prevent continued integration beyond the limit. The input to the limiter ($\dot{y}_{\text{des}}$) is called the desired rate of change of the controlled variable (Enns et al. 1996).

The closed loop transfer function is

$$\frac{y}{y_c} = \frac{K_b(f_c s + f_i K_b)}{s^2 + K_b s + f_i K_b^2}$$

and the pilot produces the commands, (y_c) with cockpit inceptors, e.g., sticks, pedals.

The control system robustness can be adjusted with the choices made for y , K_b , f_i , and f_c .

These desired dynamics are utilized in all of the examples to follow. In the following, we use dynamic inversion (Enns et al. 1996; Wacker et al. 2001) to algebraically manipulate the equations of motion into the equivalent of the integrator for y in Fig. 2.

Pure Roll Motion Example

With algebraic manipulations called dynamic inversion we can use the pure integrator results in the previous section for the pure roll motion example. For the controlled variable $y = p$, given a measurement of the state $x = p$ and values for L_p and $L_{\delta a}$, we simply solve for the input ($u = \delta_a$) that gives the desired rate of change of the output $\dot{y}_{\text{des}} = \dot{p}_{\text{des}}$. The solution is

$$\delta_a = L_{\delta a}^{-1}(\dot{p}_{\text{des}} - L_p p)$$

Since $L_{\delta a}$ and L_p vary with air density and airspeed, we are motivated to schedule these portions of the control law accordingly.

Short Period Example

Similar algebraic manipulations use the general state space notation

$$\dot{x} = Ax + Bu$$

$$y = Cx$$

We want to solve for u to achieve a desired rate of change of y , so we start with

$$\dot{y} = CAx + CBu$$

If we can invert CB , i.e., it is not zero, for the short period case, we solve for u with

$$u = (CB)^{-1}(\dot{y}_{\text{des}} - CAx)$$

Implementation requires a measurement of the state, x and models for the matrices CA and CB .

The closed loop poles include the open loop zeros of the transfer function $\frac{y(s)}{u(s)}$ (zero dynamics) in addition to the roots of the desired dynamics characteristic equation. Closed loop stability requires stable zero dynamics. The zero dynamics have an impact on control system robustness and can influence the precise choice of y .

When $y = q$, the control law includes the following dynamic inversion equation

$$\delta_e = M_{\delta_e}^{-1}(\dot{q}_{\text{des}} - M_q q - M_\alpha \alpha)$$

and the open loop zero is $Z_\alpha - Z_{\delta_e} M_{\delta_e}^{-1} M_\alpha$, which in almost every case of interest is a negative number.

Note that there are no restrictions on the open loop poles. This control law is effective and

practical in stabilization of an aircraft with an open loop unstable short period mode.

Since M_{δ_e} , M_q and M_α vary with air density and airspeed we are motivated to schedule these portions of the control law accordingly.

When $y = \alpha$, the zero dynamics are not suitable as closed loop poles. In this case, the pitch rate controller described above is the inner loop and we apply dynamic inversion a second time as an outer loop (Enns and Keviczky 2006) where we approximate the angle-of-attack dynamics with the simplification that pitch rate has reached steady state, i.e., $\dot{q} = 0$ and regard pitch rate as the input ($u = q$) and angle-of-attack as the controlled variable ($y = \alpha$). The approximate equation of motion is

$$\begin{aligned}\dot{\alpha} &= Z_\alpha \alpha + q - Z_{\delta_e} M_{\delta_e}^{-1} (M_\alpha \alpha + M_q q) \\ &= (Z_\alpha - Z_{\delta_e} M_{\delta_e}^{-1} M_\alpha) \alpha \\ &\quad + (1 - Z_{\delta_e} M_{\delta_e}^{-1} M_q) q\end{aligned}$$

This equation is inverted to give

$$\begin{aligned}q_c &= (1 - Z_{\delta_e} M_{\delta_e}^{-1} M_q)^{-1} \\ &\quad \left[\dot{\alpha}_{\text{des}} - (Z_\alpha - Z_{\delta_e} M_{\delta_e}^{-1} M_\alpha) \alpha \right]\end{aligned}$$

q_c obtained from this equation is passed to the inner loop as a command, i.e., y_c of the inner loop.

Lateral-Directional Example

If we choose the two angular rates as the controlled variables (p, r), then the zero dynamics are favorable. We use the same proportional plus integral desired dynamics in Fig. 2 but there are two signals represented by each wire (one associated with p and the other r).

The same state space equations are used for the dynamic inversion step but now CA and CB are 2×4 and 2×2 matrices, respectively instead of scalars. The superscript in $u = (CB)^{-1} (\dot{y}_{\text{des}} - CAx)$ now means matrix inverse instead of reciprocal. The zero dynamics are assessed with the

transmission zeros of the matrix transfer function $(p, r)/(\delta_a, \delta_r)$.

In the practical case where the aileron and rudder are limited, it is possible to place a higher priority on solving one equation vs. another if the equations are coupled, by proper allocation of the commands to the control surfaces which is called control allocation (Enns 1998). In these cases, we use a constrained optimization approach

$$\min_{u_{\min} \leq u \leq u_{\max}} ||CBu - (\dot{y}_{\text{des}} - CAx)||$$

instead of the matrix inverse followed by a limiter. In cases where there are redundant controls, i.e., the matrix CB has more columns than rows, we introduce a preferred solution, u_p and solve a different constrained optimization problem

$$\min_{CBu + CAx = \dot{y}_{\text{des}}} ||u - u_p||$$

to find the solution that solves the equations that is closest to the preferred solution. We utilize weighted norms to accomplish the desired priority.

An outer loop to control the attitude angles (μ, β) can be obtained with an approach analogous to the one used in the previous section.

Nonlinear Example

Dynamic inversion can be used directly with the nonlinear equations of motion (Enns et al. 1996; Wacker et al. 2001). General equations of motion, e.g., 6 degree-of-freedom rigid body can be expressed with $\dot{x} = f(x, u)$ and the controlled variable is given by $y = h(x)$. With the chain rule of calculus we obtain

$$\dot{y} = \frac{\partial h}{\partial x}(x) f(x, u)$$

and for a given $\dot{y} = \dot{y}_{\text{des}}$ and (measured) x we can solve this equation for u either directly or approximately. In practice, the first order Taylor Series approximation is effective

$$\dot{y} \cong a(x, u_0) + b(x, u_0)(u - u_0)$$

where u_0 is typically the past value of u , in a discrete implementation. As in the previous example, Fig. 2 can be used to obtain $\dot{y}_{des}$. The terms $a(x, u_0) - b(x, u_0)u_0$ and $b(x, u_0)$ are analogous to the terms CAx and the matrix CB , respectively. Control allocation can be utilized in the same way as discussed above. The zero dynamics are evaluated with transmission zeros at the intended operating points. Outer loops can be employed in the same manner as discussed in the previous section.

The control law with this approach utilizes the equations of motion which can include table lookup for aerodynamics, propulsion, mass properties, and reference geometry as appropriate. The raw aircraft data or an approximation to the data takes the place of gain schedules with this approach.

Summary and Future Directions

Flight control is concerned with tracking commands for angular rates. The commands may come directly from the pilot or indirectly from the pilot through an outer loop, where the pilot directly commands the outer loop. Feedback control enables stabilization of aircraft that are inherently unstable and provides disturbance rejection and insensitive closed-loop response in the face of uncertain or varying vehicle dynamics. Proportional and integral control provide these benefits of feedback. The aircraft dynamics are significantly different for low altitude and high speed compared to high altitude and low speed and so portions of the control law are scheduled. Aircraft do exhibit coupling between axes and so multivariable feedback loop approaches are effective. Nonlinearities in the form of limits (noninvertible) and nonlinear expressions, e.g., trigonometric, polynomial, and table look-up (invertible) are present in flight control development. The dynamic inversion approach has been shown to include the traditional feedback control principles, systematically develops the equivalent of the gain schedules, applies to multivariable systems, applies to invertible nonlinearities, and can be

used to avoid issues with noninvertible nonlinearities to the extent it is physically possible.

Future developments will include adaptation, reconfiguration, estimation, and nonlinear analyses. Adaptive control concepts will continue to mature and become integrated with approaches such as dynamic inversion to deal with unstructured or nonparameterized uncertainty or variations in the aircraft dynamics. Parameterized uncertainty will be incorporated with near real time reconfiguration of the aircraft model used as part of the control law, e.g., reallocation of control surfaces after an actuation failure. State variables used as measurements in the control law will be estimated as well as directly measured in nominal and sensor failure cases. Advances in nonlinear dynamical systems analyses will create improved intuition, understanding, and guidelines for control law development.

Application of Systems and Control Theory to Quantum Engineering

Naoki Yamamoto

Department of Applied Physics and
Physico-Informatics, Keio University,
Yokohama, Japan

Abstract

This entry is devoted to show that some quantum engineering problems, state transfer, state protection, non-demolition measurement, and back-action-evading measurement, can be formulated and solved within the framework of linear systems and control theory.

Keywords

Quantum information · Linear systems ·
Controllability and observability

Introduction

Systems and control theory has established vast analytic and computational methods for analyzing/synthesizing a system of the form

$$\dot{x} = Ax + Bu, \quad y = Cx + Du. \quad (1)$$

Surprisingly, many important quantum systems, such as optical, superconducting, and atomic systems, can be modeled with linear dynamical equations. In those cases, x denotes the vector of variables (called “observables” in quantum mechanics) such as the position q and the momentum p of a particle; note that these variables are operators, not scalar-valued quantities, which thus do not commute with each other, e.g., $qp - pq = i$. Also, if one aims to control the system or extract information from it, typically an electromagnetic field called the probe field is injected into the system; u denotes the vector of probe variables such as amplitude and phase of the field. y denotes the variables of (reflected or transmitted) output field or the

signal obtained as a result of measurement on the output field. The matrices (A, B, C, D) are determined from the system. The goal of this entry is to show that some quantum engineering problems can be well formulated and solved within the framework of systems and control theory. See Nurdin and Yamamoto (2017) for other applications to quantum engineering.

State Transfer

To realize quantum information technology such as quantum computation and quantum communication, it is very important to devise a scalable hybrid system composed of optical and solid-state systems, to compensate for their advantages and disadvantages; the main advantage of solid-state systems such as superconducting devices is that it is relatively easy to generate a highly non-linear coupling and produce a genuine quantum state, but the disadvantage is that sending those states to other places is hard; on the other hand, optical systems such as an optical fiber network is suited to efficiently sending a quantum state to several sites, but in general, the quantumness of optical states is weak, due to the weak non-linearity of optical systems. A key technique to connect these different systems is state transfer from optics to solid state and vice versa. In fact there have been a number of research studies on this topic, including the analysis of particular systems achieving perfect state transfer.

Yamamoto and James (2014) demonstrated a system theoretic approach for designing an input single-photon state that can be perfectly transferred to a general SISO passive linear quantum system of the form

$$\dot{x} = Ax - C^\dagger u, \quad y = Cx + u,$$

where $A = -i\Omega - C^\dagger C/2$ with Ω a Hermitian matrix and C a complex row vector describing the system-probe coupling. The idea is simple; the perfect input $u(t)$ (more precisely $u(t)$ is the pulse shape of the input single-photon state) should be the one such that $y(t) = 0$ always holds for the duration of the transfer, meaning that the input field is completely absorbed into the

solid-state system with variable $x(t)$, and accordingly, the output field must be a vacuum. Then $y(t) = 0$, ($t \leq t_1$) readily leads to $u^{\text{opt}}(t) = -x(t_1)^\top e^{-A^*(t-t_1)} C^\top$ ($\bullet^\dagger$, $\bullet^\top$, and $\bullet^*$ represent the Hermitian conjugate, transpose, and element-wise complex conjugate, respectively). This special type of system, whose output is always zero, is said to have the *zero dynamics* in the systems and control theory, which are completely characterized by the zeros of the transfer function in the linear case; Yamamoto et al. (2016) used this fact to extend the above result to the multi-input case. Moreover, Nakao and Yamamoto (2017) considered an optimal control problem where an additional control signal is introduced through the A matrix (more precisely through the system Hamiltonian) for reducing the complexity of the desired pulse shape $u^{\text{opt}}(t)$.

State Protection

Once a desirable quantum state is generated in a solid-state system by, e.g., the state transfer method described above, the next task is to manipulate and store that state. This process must be carried out in a subsystem isolated from the probe field as well as the surrounding environment. This subsystem is called a *decoherence-free subsystem (DFS)*.

A contribution of systems and control theory is that it can offer a convenient and general characterization of DFS, particularly in the linear case. The point is that a DFS is a system that is not affected by the probe and environment fields, and also it cannot be monitored from outside; in the language of systems and control, a DFS is a u -uncontrollable and y -unobservable subsystem for the system (1). Based on this fact, Yamamoto (2014) gave a simple necessary and sufficient condition for the general linear quantum system to have a DFS. An example is an atomic ensemble described by the following linear dynamical equation:

$$\begin{bmatrix} \dot{x}_1 \\ \dot{x}_2 \\ \dot{x}_3 \end{bmatrix} = \begin{bmatrix} -\kappa & ig & 0 \\ ig & -i\delta & i\omega \\ 0 & i\omega^* & 0 \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \\ x_3 \end{bmatrix} - \begin{bmatrix} \sqrt{2\kappa} \\ 0 \\ 0 \end{bmatrix} u, \quad (2)$$

$$y = \sqrt{2\kappa}x_1 + u,$$

where (x_1, x_2, x_3) are the system variables (spin operators) and $(\kappa, g, \delta, \omega)$ are the system parameters. Clearly, x_3 is decoupled from both the input and output fields when $\omega = 0$; thus, it functions as a DFS. This system can be used as a quantum memory as follows. By setting $\omega \neq 0$ and using the technique described in the previous subsection, one can transfer an input photon state to x_3 ; then by setting $\omega = 0$, that state is preserved. If one wants to use the stored state later, then the DFS again couples with the probe field and releases the state. Also, Yamamoto (2014) considered a linear system having a two-dimensional DFS and showed a simple manipulation of the DFS state.

An interesting related problem is how to engineer a system that contains a DFS. *Coherent feedback (CF)* control, the method connecting some quantum subsystems through electromagnetic fields in a feedback way without introducing any measurement process, gives a solution for this purpose. In fact it was demonstrated in Yamamoto (2014) that, actually, the CF method is applied to engineer a linear system having a DFS.

Quantum Non-demolition Measurement

There is a need to precisely determine and control a particular element of x , say x_s , such as the motional variable of a mechanical oscillator and the number of photons in an optical cavity. For this purpose, rich information on x_s should be available via some measurement on the output probe field, while x_s should not be perturbed by the corresponding input probe field; if there exists such a variable x_s , then it is called a *quantum non-demolition (QND)* variable, and the corresponding measurement schematic is called the QND measurement. The system theoretic formulation of a QND variable is that x_s is u -uncontrollable and y -observable. Thanks to this general characterization, it is possible to take several new approaches for analyzing and synthesizing QND variables. For instance, using a special type of CF control, one can create a QND variable which does not exist in the original uncontrolled system (Yamamoto 2014).

Back-Action-Evading Measurement

To detect a very small (i.e., quantum level) signal such as a gravitational wave and a tiny magnetic field, it is important to devise a special type of detector that fully takes into account quantum mechanical property; the *back-action-evading* (BAE) measurement is one such established method. Here we describe the problem for the system (1). This system functions as a sensor for a small signal, in such a way that the signal drives some y -observable elements of x . In the case where the probe field is single mode, the input is represented as $u = (Q, P)$, where Q and P are the amplitude and phase variables of the input field; these are the so-called conjugate variables satisfying the Heisenberg uncertainty relation $\langle \Delta Q^2 \rangle \langle \Delta P^2 \rangle \geq 1$. Also now the corresponding measurement output is given by $y = Cx + Q$. Hence it seems that S/N increases by reducing the magnitude of the noise Q , but this induces an increase of P from the abovementioned Heisenberg uncertainty relation; for this reason, P is called the back-action noise. Consequently, in the usual setup of the detector, the noise level of y is lower bounded by the so-called *standard quantum limit* (SQL).

There have been a number of proposals for the detector configuration that can beat the SQL and achieve better sensitivity of the signal, that is, the aim is to devise a BAE detector such that y is not affected by P . In the language of systems and control theory, this condition is that the transfer function from P to y , $\Xi(s)$, is zero for all s . This is equivalent to the geometric condition that the y -observable subspace is contained in the P -uncontrollable subspace. Using this characterization, (Yamamoto 2014; Yokotera and Yamamoto 2016) gave a new BAE force detector, based on the CF control. Moreover, in Yokotera and Yamamoto (2016), the BAE problem is formulated as the optimization problem $\|\Xi(s)\| \rightarrow \min.$ for synthesizing a detector that beats the SQL.

Abstract

This entry provides an overview of the problems addressed by DES theory, with an emphasis on their connection to various application contexts. The primary intentions are to reveal the caliber and the strengths of this theory and to direct the interested reader, through the listed citations, to the corresponding literature. The concluding part of the article also identifies some remaining challenges and further opportunities for the area.

Keywords

Discrete event systems · Applications

Introduction

Discrete event system (DES) theory ► [Models for Discrete Event Systems: An Overview](#) Christos Cassandras, (Cassandras and Lafor-tune 2008; Seatzu et al. 2013) emerged in the late 1970s/early 1980s from the effort of the controls community to address the control needs of applications concerning some complex production and service operations, like those taking place in manufacturing and other workflow systems, telecommunication and data processing systems, and transportation systems. These operations were seeking the ability to support higher levels of efficiency and productivity and more demanding notions of quality of product and service. At the same time, the thriving computing technologies of the era, and in particular the emergence of the microprocessor, were cultivating, and to a significant extent supporting, visions of ever-increasing automation and autonomy for the aforementioned operations. The DES community set out to provide a systematic and rigorous understanding of the dynamics that drive the aforementioned operations and their complexity and to develop a control paradigm that would define and enforce the target behaviors for those environments in an effective and robust manner.

In order to address the aforementioned objectives, the controls community had to extend its methodological base, borrowing concepts, models, and tools from other disciplines. Among these disciplines, the following two played a particularly central role in the development of the DES theory: (i) theoretical computer science (TCS) and (ii) operations research (OR). As a new research area, DES thrived on the analytical strength and the synergies that resulted from the rigorous integration of the modeling frameworks that were borrowed from TCS and OR. Furthermore, the DES community substantially extended those borrowed frameworks, bringing in them

many of its control-theoretic perspectives and concepts.

In general, DES-based approaches are characterized by (i) their emphasis on a rigorous and formal representation of the investigated systems and the underlying dynamics; (ii) a double focus on time-related aspects and metrics that define traditional/standard notions of performance for the considered systems but also on a more behaviorally oriented analysis that is necessary for ensuring fundamental notions of “correctness,” “stability,” and “safety” of the system operation, especially in the context of the aspired levels of autonomy; (iii) the interplay between the two lines of analysis mentioned in item (ii) above and the further connection of this analysis to structural attributes of the underlying system; and (iv) an effort to complement the analytical characterizations and developments with design procedures and tools that will provide solutions provably consistent with the posed specifications and effectively implementable within the time and other resource constraints imposed by the “real-time” nature of the target applications.

The rest of this entry overviews the current achievements of DES theory with respect to (w.r.t.) the different classes of problems that have been addressed by it and highlights the potential that is defined by these achievements for a range of motivating applications. On the other hand, the constricted nature of this entry does not allow an expansive treatment of the aforementioned themes. Hence, the provided coverage is further supported and supplemented by an extensive list of references that will connect the interested reader to the relevant literature.

A Tour of DES Problems and Applications

DES-Based Behavioral Modeling, Analysis, and Control

The basic characterization of behavior in the DES theoretic framework is through the various event sequences that can be generated by the underlying system. Collectively, these sequences are known as the (formal) language generated by

the plant system, and the primary intention is to restrict the plant behavior within a subset of the generated event strings. The investigation of this problem is further facilitated by the introduction of certain mechanisms that act as formal representations of the studied systems, in the sense that they generate the same strings of events (i.e., the same formal language). Since these models are concerned with the representation of the event sequences that are generated by DES, and not by the exact timing of these events, they are frequently characterized as *untimed* DES models. In the practical applications of DES theory, the most popular such models are the finite state automaton (FSA) (Hopcroft and Ullman 1979; Cassandras and Lafortune 2008), ► [Supervisory Control of Discrete-Event Systems](#) W. Murray Wonham, ► [Diagnosis of Discrete Event Systems](#) Stéphane Lafortune and the Petri net (PN) (Murata 1989; Cassandras and Lafortune 2008), ► [Modeling, Analysis, and Control with Petri Nets](#) Manuel Silva.

In the context of DES applications, these modeling frameworks have been used to provide succinct characterizations of the underlying event-driven dynamics and to design controllers, in the form of supervisors, that will restrict these dynamics so that they abide to safety, consistency, fairness, and other similar considerations ► [Supervisory Control of Discrete-Event Systems](#) W. Murray Wonham. As a more concrete example, in the context of contemporary manufacturing, DES-based behavioral control – frequently referred to as supervisory control (SC) – has been promoted as a systematic methodology for the synthesis and verification of the control logic that is necessary for the support of the so-called SCADA (supervisory control and data acquisition) function. This control function is typically implemented through the programmable logic controllers (PLCs) that have been employed in contemporary manufacturing shop floors, and DES SC theory can support it (i) by providing more rigor and specificity to the models that are employed for the underlying plant behavior and the imposed specifications and (ii) by offering the ability to synthesize control policies that are provably correct by construction. Some example

works that have pursued the application of DES SC along these lines can be found in Balemi et al. (1993), Brandin (1996), Park et al. (1999), Chandra et al. (2003), Endsley et al. (2006), and Andersson et al. (2010).

On the other hand, the aforementioned activity has also defined a further need for pertinent interfaces that will translate (a) the plant structure and the target behavior to the necessary DES-theoretic models and (b) the obtained policies to PLC executables. This need has led to a line of research, in terms of representational models and computational tools, which is complementary to the core DES developments described in the previous paragraphs. Indicatively we mention the development of GRAFCET (David and Alla 1992) and of the sequential function charts (SFCs) (Lewis 1998) from the earlier times, while some more recent endeavor along these lines is reported in Wightkin et al. (2011) and Alenljung et al. (2012) and the references cited therein.

Besides its employment in the manufacturing domain, DES SC theory has also been considered for the coordination of the communicating processes that take place in various embedded systems (Feng et al. 2007); the systematic validation of the embedded software that is employed in various control applications, ranging from power systems and nuclear plants to aircraft and automotive electronics (Li and Kumar 2012); the synthesis of the control logic in the electronic switches that are utilized in telecom and data networks; and for the modeling, analysis, and control of the operations that take place in health-care systems (Sampath et al. 2008). Wassying et al. (2011) gives a very interesting account of the gains but also the extensive challenges, experienced by a team of researchers who have tried to apply formal methods, similar to those that have been promoted by the behavioral DES theory, to the development and certification of the software that manages some safety critical operations for Canadian nuclear plants.

Apart from control, untimed DES models have also been employed for the diagnosis of critical events, like certain failures, that cannot be observed explicitly, but their occurrence can be inferred from some resultant behavioral

patterns (Sampath et al. 1996) ► [Diagnosis of Discrete Event Systems](#) Stephane Lafortune. More recently, the relevant methodology has been extended with prognostic capability (Kumar and Takai 2010), while an interesting variation of it addresses the “dual” problem that concerns the design of systems where certain events or behavioral patterns must remain undetectable by an external observer who has only partial observation of the system behavior; this last requirement has been formally characterized by the notion of “opacity” in the relevant literature, and it finds application in the design and operation of secure systems (Dubreil et al. 2010; Saboori and Hadjicostis 2012, 2014; Wu and Lafortune 2013) ► [Opacity of Discrete Event Systems](#) Christoforos Hadjicostis.

Dealing with the Underlying Computational Complexity

As revealed from the discussion of the previous paragraphs, many of the applications of DES SC theory concern the integration and coordination of behavior that is generated by a number of interacting components. In these cases, the formal models that are necessary for the description of the underlying plant behavior may grow their size very fast, and the algorithms that are involved in the behavioral analysis and control synthesis may become practically intractable. Nevertheless, the rigorous methodological base that underlies DES theory provides also a framework for addressing these computational challenges in an effective and structured manner.

More specifically, DES SC theory provides conditions under which the control specifications can be decomposable to the constituent plant components while maintaining the integrity and correctness of the overall plant behavior ► [Supervisory Control of Discrete-Event Systems](#) W. Murray Wonham, (2006). The aforementioned works of Brandin (1996) and Endsley et al. (2006) provide some concrete examples for the application of modular control synthesis. But there are also fundamental problems addressed by SC theory and practice that require a holistic view of the underlying plant and its operation, and thus, they are not

amenable to the aforementioned decomposing solutions. DES SC theory can provide effective and tractable solutions for many of these cases as well, by, e.g., (i) helping identify special plant structure, of practical relevance, for which the target supervisors are implementable in a computationally efficient manner, or (ii) developing customized structured approaches that can systematically trade-off the original specifications for computational tractability. Additional substantial leverage in such endeavors is provided by the availability of more than one formal framework for tackling these problems, with complementary modeling and analytical capabilities. In particular, Petri nets can be an especially useful tool in the context of these endeavors, since they (a) provide very compact representations of the underlying plant dynamics, (b) capture effectively the connection of these dynamics to the structural properties of the plant, and also (c) admit analytical techniques of a more algebraic nature that do not require an explicit enumeration of the underlying state space (Murata 1989; Holloway et al. 1997; Cabasino et al. 2013) ► [Modeling, Analysis, and Control with Petri Nets](#) Manuel Silva.

A particular application that has benefited from, and, at the same time, has significantly promoted the capabilities of DES SC theory to deal in an effective and structured manner with the high inherent complexity of the targeted behaviors, is that concerning the deadlock-free operation of many systems where a set of processes that execute concurrently and in a staged manner, are competing, at each of their processing stages, for the allocation of a finite set of reusable resources. In DES theory, this problem is known as the liveness-enforcing supervision of sequential resource allocation systems (RAS) (Reveliotis 2005; Zhou and Fanti 2004), and it underlies the operation of many contemporary applications: from the resource allocation taking place in contemporary manufacturing shop floors (Ezpeleta et al. 1995; Reveliotis and Ferreira 1996; Jeng et al. 2002) to the traveling and/or work-space negotiation in robotic systems (Reveliotis and Roszkowska 2011), automated railway (Giua et al. 2006),

and other guidelpath-based traffic systems (Reveliotis 2000), to Internet-based workflow management systems like those envisioned for e-commerce and certain banking and insurance claim processing applications (Van der Aalst 1997), and to the allocation of the semaphores that control the accessibility of shared resources by concurrently executing threads in parallel computer programs (Liao et al. 2013). A comprehensive and systematic introduction to the DES-based modeling of RAS and the problem of their liveness-enforcing supervision can be found in Reveliotis (2017).

Closing the above discussion on the ability of DES theory to address effectively the complexity that underlies the DES SC problem, we should point out that the same merits of the theory have also enabled the effective management of the complexity that underlies problems related to the performance modeling and control of the various DES applications. We shall return to this capability in the next subsection that discusses the achievements of DES theory in this domain.

DES Performance Control and the Interplay Among Structure, Behavior, and Performance

DES theory is also interested in the performance modeling, analysis, and control of its target applications w.r.t. time-related aspects like throughput, resource utilization, experienced latencies, and congestion patterns. To support this type of analysis, the untimed DES behavioral models are extended to their *timed* versions. This extension takes place by endowing the original untimed models with additional attributes that characterize the experienced delays between the activation of an event and its execution (provided that it is not preempted by some other conflicting event). Timed models are further classified by the extent and the nature of the randomness that is captured by them. A basic such categorization is between deterministic models, where the aforementioned delays take fixed values for every event, and stochastic models which admit more general distributions. From an application standpoint, timed DES models connect DES theory to the multitude of applications that have been

addressed by dynamic programming, stochastic control, and scheduling theory (Bertsekas 1995; Meyn 2008; Pinedo 2002), Control and Optimization of Stochastic Discrete Event Systems Xiren Cao. Also, in their most general definition, stochastic DES models provide the theoretical foundation of discrete event simulation (Banks et al. 2009).

Similar to the case of behavioral DES theory, a practical concern that challenges the application of timed DES models for performance modeling, analysis, and control is the very large size of these models, even for fairly small systems. DES theory has tried to circumvent these computational challenges through the development of methodology that enables the assessment of the system performance, over a set of possible configurations, from the observation of its behavior and the resultant performance at a single configuration. The required observations can be obtained through simulation, and in many cases, they can be collected from a single realization – or sample path – of the observed behavior; but then, the considered methods can also be applied on the actual system, and thus, they become a tool for real-time optimization, adaptation, and learning.

Collectively, the aforementioned methods define a “sensitivity”-based approach to DES performance modeling, analysis, and control (Cassandras and Lafortune 2008), ▶ [Perturbation Analysis of Discrete Event Systems](#) Yorai Wardi. Historically, DES sensitivity analysis originated in the early 1980s in an effort to address the performance analysis and optimization of queueing systems w.r.t. certain structural parameters like the arrival and processing rates (Ho and Cao 1991). But the current theory addresses more general stochastic DES models that bring it closer to broader endeavors to support incremental optimization, approximation, and learning in the context of stochastic optimal control (Cao 2007; Wardi et al. 2018). Some particular applications of DES sensitivity analysis for the performance optimization of production, telecom, and computing systems can be found in Cassandras and Strickland (1988), Cassandras (1994), Panayiotou and Cassandras (1999), Homem-de Mello et al. (1999), Fu and

Xie (2002), Santoso et al. (2005), and Li and Reveliotis (2015).

Another interesting development in time-based DES theory is the theory of $(\max,+)$ algebra (Baccelli et al. 1992; Hardouin et al. 2018). In its practical applications, this theory addresses the timed dynamics of systems that involve the synchronization of a number of concurrently executing processes with no conflicts among them, and it provides important structural results on the factors that determine the behavior of these systems in terms of the occurrence rates of various critical events and the experienced latencies among them. Motivational applications of $(\max,+)$ algebra can be traced in the design and control of telecommunication and data networks, manufacturing, and railway systems, and more recently, the theory has found considerable practical application in the computation of repetitive/cyclical schedules that seek to optimize the throughput rate of automated robotic cells and of the cluster tools that are used in semiconductor manufacturing (Park et al. 1999; Lee 2008; Kim and Lee 2012).

Both, sensitivity-based methods and the theory of $(\max,+)$ algebra, that were discussed in the previous paragraphs, are enabled by the explicit, formal modeling of the DES structure and behavior in the pursued performance analysis and control. This integrative modeling capability that is supported by DES theory also enables a profound analysis of the impact of the imposed behavioral-control policies upon the system performance and, thus, the pursuance of a more integrative approach to the synthesis of the behavioral and the performance-oriented control policies that are necessary for any particular DES instantiation. This is a rather novel topic in the relevant DES literature, and some recent works in this direction can be found in Cao (2005), Markovski and Su (2013), David-Henriet et al. (2013), Li and Reveliotis (2015), and Li and Reveliotis (2016).

The Roles of Abstraction and Fluidification

The notions of “abstraction” and “fluidification” play a significant role in mastering the complexity that arises in many DES applications. Furthermore, both of these concepts have an important

role in defining the essence and the boundaries of DES-based modeling.

In general systems theory, abstraction can be broadly defined as the effort to develop simplified models for the considered dynamics that retain, however, adequate information to resolve the posed questions in an effective manner. In DES theory, abstraction has been pursued w.r.t. the modeling of, both, the timed and untimed behavior, giving rise to hierarchical structures and models. A theory for hierarchical SC is presented in Wonham (2006), while some applications of hierarchical SC in the manufacturing domain are presented in Hill et al. (2010) and Schmidt (2012). In general, hierarchical SC relies on a “spatial” decomposition that tries to localize/encapsulate the plant behavior into a number of modules that interact through the communication structure that is defined by the hierarchy. On the other hand, when it comes to timed DES behavior and models, a popular approach seeks to define a hierarchical structure for the underlying decision-making process by taking advantage of the different time scales that correspond to the occurrence of the various event types. Some particular works that formalize and systematize this idea in the application context of production systems can be found in Gershwin (1994) and Sethi and Zhang (1994) and the references cited therein.

In fact, the DES models that have been employed in many application areas can be perceived themselves as abstractions of dynamics of a more continuous, time-driven nature, where the underlying plant undergoes some fundamental (possibly structural) transition upon the occurrence of certain events that are defined either endogenously or exogenously w.r.t. these dynamics. The combined consideration of the discrete event dynamics that are generated in the manner described above, with the continuous, time-driven dynamics that characterize the modalities of the underlying plant, has led to the extension of the original DES theory to the so-called hybrid systems theory. Hybrid systems theory is itself very rich, and it is covered in another section of this encyclopedia (see also ► [Discrete Event Systems and Hybrid Systems](#),

Connections Between Alessandro Giua). From an applications standpoint, it increases substantially the relevance of the DES modeling framework and brings this framework to some new and exciting applications. Some of the most prominent such applications concern the coordination of autonomous vehicles and robotic systems, and a nice anthology of works concerning the application of hybrid systems theory in this particular application area can be found in the IEEE Robotics and Automation magazine of September 2011. These works also reveal the strong affinity that exists between hybrid systems theory and the DES modeling paradigm. Along similar lines, hybrid systems theory underlies also the endeavors for the development of the automated highway systems that have been explored for the support of the future urban traffic needs (Horowitz and Varaiya 2000; Fleck et al. 2016). Finally, hybrid systems theory and its DES component have been explored more recently as potential tools for the formal modeling and analysis of the molecular dynamics that are studied by systems biology (Curry 2012).

Fluidification, on the other hand, is the effort to represent as continuous flows, dynamics that are essentially of discrete event type, in order to alleviate the computational challenges that typically result from discreteness and its combinatorial nature. The resulting models serve as approximations of the original dynamics; frequently, they have the formal structure of hybrid systems, and they define a basis for developing “relaxations” for the originally addressed problems. Usually, their justification is of an ad hoc nature, and the quality of the established approximations is empirically assessed on the basis of the delivered results (by comparing these results to some “baseline” performance). There are, however, a number of cases where the relaxed fluid model has been shown to retain important behavioral attributes of its original counterpart (Dai 1995). Furthermore, some recent works have investigated more analytically the impact of the approximation that is introduced by these models on the quality of the delivered results (Wardi and Cassandras 2013), while an additional important extension of the fluid modeling framework for

DES is through the notion of “stochastic flow models (SFM),” which allow the flow rates themselves to be random processes. Some works introducing the SFM framework and providing a first set of results for it can be found in Cassandras et al. (2002) and Sun et al. (2004), while a brief but more tutorial exposition of this framework is provided in Wardi et al. (2018). On the other hand, some works exemplifying the application of fluidification in the DES-theoretic modeling frameworks, and the potential advantages that this approach brings in various application contexts, can be found in Srikant (2004), Meyn (2008), David and Alla (2005), Cassandras and Yao (2013), and Ibrahim and Reveliotis (2019). Finally, the work of Vázquez et al. (2013) provides a nice introduction on the pursuance of the “fluidification” concept in the Petri net modeling framework, while the recent work of Ibrahim and Reveliotis (2018) demonstrates very vividly how the corresponding results enable a synergistic employment of all the different representations of DES behavior that have been discussed in this document, in a totally integrative and seamless manner.

Summary and Future Directions

The discussion of the previous section has revealed the extensive application range and potential of DES theory and its ability to provide structured and rigorous solutions to complex and sometimes ill-defined problems. On the other hand, the same discussion has revealed the challenges that underlie many of the DES applications. The complexity that arises from the intricate and integrating nature of most DES models is perhaps the most prominent of these challenges. This complexity manifests itself in the involved computations but also in the need for further infrastructure, in terms of modeling interfaces and computational tools, that will render DES theory more accessible to the practitioner.

The DES community is aware of this need, and the last few years have seen the development of a number of computational platforms that seek to implement and leverage the existing theory

by connecting it to various application settings; indicatively, we mention DESUMA (Ricker et al. 2006), SUPREMICA (Akeson et al. 2006), and TCT (Feng and Wonham 2006), that support DES behavioral modeling, analysis, and control along the lines of DES SC theory, while the website entitled “The Petri Nets World” has an extensive database of tools that support modeling and analysis through untimed and timed variations of the Petri net model. Model checking tools, like SMV and NuSPIN, which are used for verification purposes, are also important enablers for the practical application of DES theory, and, of course, there are a number of programming languages and platforms, like Arena, AutoMod, Simio, and SimEvents that support discrete event simulation (SimEvents also supports simulation of hybrid systems). However, with the exception of the discrete event simulation software, which is a pretty mature industry, the rest of the aforementioned endeavors currently evolve primarily within the academic and the broader research community. Hence, a remaining challenge for the DES community is the strengthening and expansion of the aforementioned computational platforms to robust and user-friendly computational tools. The availability of such industrial strength computational tools, combined with the development of a body of control engineers well-trained in DES theory, will be catalytic for bringing all the developments that were described in the earlier parts of this document even closer to the industrial practice.

Approximate Dynamic Programming (ADP)

Paul J. Werbos

National Science Foundation, Arlington, VA, USA

Abstract

Approximate dynamic programming (ADP or RLADP) includes a wide variety of general methods to solve for optimal decision and control in the face of complexity, nonlinearity, stochasticity, and/or partial observability. This entry first reviews methods and a few key applications across decision and control engineering (e.g., vehicle and logistics control), computer science (e.g., AlphaGo), operations research, and connections to economics, neuropsychology, and animal behavior. Then it summarizes a sixfold mathematical taxonomy of methods in use today, with pointers to the future.

Paul J. Werbos has retired.

Introduction**What Is ADP: A General Definition of ADP and Notation**

Logically, ADP is that branch of applied mathematics which develops and studies general purpose methods for optimal decision or control over dynamical systems which may or may not be subject to stochastic disturbance, partial observability, nonlinearity, and complexity, for situations where exact dynamic programming (DP) is too expensive to perform directly. Many ADP methods assume the case of discrete time t , but others address the case of continuous time t . ADP tries to learn or converge to the exact DP solution as accurately and as reliably as possible, but some optimization problems are more difficult than others. In some applications, it is useful enough to start from the best available controller based on more classical methods and then use ADP iteration to improve that controller. In other applications, users of ADP have obtained results so accurate that they can claim to have designed fully robust nonlinear controllers, by solving (accurately enough) the Hamilton-Jacobi-Bellman (HJB) equation for the control task under study.

Let us write the state of a dynamical system at time t as the vector $\underline{x}(t)$, and the vector of observations as $\underline{y}(t)$. (Full observability is just the special case where $\underline{y}(t) = \underline{x}(t)$.) Let us define a *policy* $\underline{\pi}$ as a control rule, function, or procedure used to calculate the vector $\underline{u}(t)$ of controls (physical actions, decisions) by:

$$\underline{u}(t) = \underline{\pi}(\{y(\tau), \tau \leq t\}) \quad (1)$$

The earliest useful ADP methods (White and Sofge 1992) asked the user to supply a control rule $\underline{\pi}(\underline{y}(t), \underline{\alpha})$ or $\underline{\pi}(\underline{R}(t), \underline{\alpha})$, where $\underline{\alpha}$ is the set of parameters or weights in the control rule, and where $\underline{R}(t)$ may either be an estimate of the state $\underline{x}(t)$, or, more generally, a representation of the “belief state” which is defined as the probability density function $\text{Pr}(\underline{x}(t) | \{y(\tau), \tau \leq t\})$. These types of methods may logically be called “adaptive policy methods.” Of course, the user is free to try several candidate control rules. Just as he or she might try different stochastic models in trying to identify an unknown plant and compare to see which policy works best in simulation. Long before the term “neurodynamic programming” was coined, the earliest ADP designs included the use of universal function approximators such as neural networks to try to approximate the best possible function $\underline{\pi}$.

Later work on ADP developed applications in areas such as missile interception (like the work of Balakrishnan included in Lewis and Liu (2013)) and in complex logistics (like the paper by L. Werbos, Kozma et al on Metamodeling) where it works better simply to calculate the optimal action $u(t)$ at each time t , exploiting other aspects of the standard DP tools. In the future, hybrid methods may be developed which modify a global control law on the fly, similar to the moving intercept trick used by McAvoy with great success in model predictive control (MPC) (White and Sofge 1992). These may be called hybrid policy methods.

The earliest ADP methods (White and Sofge 1992) focused entirely on the case of discrete time. In that case, the task of ADP is to find the policy π which maximizes (or minimizes) the expected value of:

$$J_0(x(t)) = \sum_{\tau=t}^T \frac{U(x(\tau), u(\tau))}{(1+r)^{\tau-t}}, \quad (2)$$

where U is a utility function (or cost function), where T is a termination time (which may be infinity), where r is a discount factor (interest rate), and where future values of $\underline{x}$ and $\underline{u}$ are stochastic functions of the policy π .

As with any optimization problem or control design, it is essential for the user to think hard about what he or she really wants and what the ultimate metric of success or performance really is. The interest rate r is just as important as the utility function, in expressing what the ultimate goal of the exercise is. It often makes sense to define U as a measure of economic value added, plus a penalty function to keep the system within a broad range of controllability. With certain plants, like the dynamically unstable SR-71 aircraft, optimal performance will sometimes take advantage of giving the system “permission” to deviate from the nominal control trajectory to some degree. To solve a very tricky nonlinear control problem, it often helps to solve it first with a larger interest rate, in order to find a good starting point, and then “tighten the screws” or “extending the foresight horizon” by dialing r down to zero. Many ADP computer programs use a kind of “discount factor” $\gamma = 1/(1 + r)$, to simply programming, but there is a huge literature on decision analysis and economics on how to understand the interest rate r .

Continuous time versions of ADP have been pioneered by Frank Lewis (Lewis and Liu 2013), with extensions to differential games (such as two-player “adversarial” ADP offering strategies for worst case survival).

Varieties of ADP from Reinforcement Learning to Operations Research

In practice, there probably does not exist an integrated mathematical textbook on ADP which gives both full explanation and access to the full range of practical tools for the field as a whole. The reason for this is that nonlinear dynamic optimization problems abound in a wide variety of fields, from economics and psychology to control engineering and even to physics. The underlying mathematics and tools are universal, but even today it is important to reach across disciplines and across different approaches and terminologies to know what is available.

Prior to the late 1980s, it was well understood that “exact” DP and the obvious approximations

to DP suffer from a severe “curse of dimensionality.” Finding an exact solution to a DP task required calculations which grew exponentially, even for small tasks in the general case. In the special case of a linear plant and a quadratic utility function, the calculations are much easier; that gave rise to the vast field of linear-quadratic optimal control, discussed in other articles of this encyclopedia. Ron Howard developed iterative dynamic programming for systems with a discrete number of states; this was rigorous and universal enough that it was disseminated from operations research to mathematical economics, but it did not help with curse of dimensionality as such. Research in (mainly discrete) Markov decision processes (MDP) and partially observed MDP (POMDP) has also provided useful mathematical foundations for further work.

All of this work was well grounded in the concept of cardinal utility function, defined in the classic book *Theory of Games and Economic Behavior* by von Neumann and Morgenstern. It started from the classic work of Richard Bellman, most notably the Bellman equation, to be presented in the next section. von Neumann’s concept had deep roots in utilitarian economics and in Aristotle’s concept of “telos”; in fact, there are striking parallels between modern discussion of how to formulate a utility function and Aristotle’s discussion of “happiness” in his *Nicomachean Ethics*.

In the same early period, there was substantial independent interest in a special case of ADP called “reinforcement learning” in psychology and in artificial intelligence in computer science. Unfortunately, the same term, “reinforcement learning,” was applied to many other things as well. For example, it was sometimes used as an umbrella term for all types of optimization method, including static optimization, performed in a heuristic manner.

The original concept of “reinforcement learning” came from B.F. Skinner and his many followers, who worked to develop mathematical models to describe animal learning. Instead of a utility function, “ U ,” they developed models of animals as systems which learn to maximize a reinforcement signal, just “ r ” or “ $r(t)$,” represent-

ing the reward or punishment, pain, or pleasure, experienced by the animal. Even to this day, followers of that tradition sometimes use that notation. The work of Klopff in the tradition of Skinner was a major driver of the classic 1983 paper by Barto, Sutton, and Anderson in the IEEE Transactions on Systems, Man, and Cybernetics (SMC). This work implicitly assumed that the utility function U is not known as a function and that we only have access to its value at any time.

Many years ago, a chemical engineer said in a workshop: “I really don’t want to study all these complex mathematical details. What I really want is a black box, which I can hook up to my sensors and my actuators, and to a real time measure of performance which I can provide. I really want a black box which could do all the work of figuring out the relations between sensors and actuators, and how to maximize performance over time.” The task of reinforcement learning was seen as the task of how to design that kind of black box.

The early pioneers of artificial intelligence (AI) were well aware of reinforcement learning. For example, Marvin Minsky (in the book *Computers and Thought*) argued that new methods for reinforcement learning would be the path to true brain-like general artificial intelligence. But no such methods were available. Minsky recognized that all of the early approaches to reinforcement learning suffered from a severe curse of dimensionality and could not begin to handle the kind of complexity which brains learn to handle. AI and computer science mostly gave up on this approach at that time, just as it gave up on neural networks.

In a way, the paralysis ended in 1987, when Sutton read my paper in SMC describing how the curse of dimensionality could be overcome by treating the reinforcement learning problem as a special case of ADP and by using a combination of neural networks, backpropagation, and new approximation methods. That led to many discussions and to an NSF workshop in 1988, which for the first time brought together many of the relevant disciplines and tried to provide an integration of tools and applications. The book from that workshop, *Neural Networks for Control*, edited by Miller, Sutton, and Werbos is still

of current use. However, later workshops went further and deeper; references White and Sofge (1992) and Lewis and Liu (2013), led by the control community, provide the best comprehensive starting point for what is available from the various disciplines.

Within the relevant disciplines, there has been some important fundamental extension since the publication of Lewis and Liu (2013). The most famous extension by far was the triumph of the AlphaGo systems which learned to defeat the best human champion in Go. At the heart of that success was the use of an ADP method in the heuristic dynamic programming (HDP) group of methods, to be discussed in the next section, as tuned and applied by Sutton. However, success in a game of that complexity also depended on combining HDP with complementary techniques, which are actually being assimilated in engineering applications such as self-driving cars, pioneered at the Chinese Academy of Sciences Institute of Automation (CASIA), which is the center of China’s major new push in “the new AI.”

There has also been remarkable progress in ADP within the control field proper, especially in applications and in stability theory. Building on Lewis and Liu (2013), CASIA and Derong Liu have spawned a wide range of new applications. The new book by Liu is probably a good source, but I am not aware of a single good review of all the more recent stability work across the world. Some commentators on “the new AI” have said that China is so far ahead in engineering kinds of applications relevant to the Internet of Things that Western reviews often fail to appreciate just how much they are missing of new technologies. Off-the-shelf software for ADP tends to reflect the limited set of methods best known in computer science, simply because they tend to have more interest than engineers do in open-source software development (and in dissemination which may benefit competitors).

Within the field of operations research, Warren Powell has developed a comprehensive framework and textbook well-informed by discussions across the disciplines and by a wide range of applications from logistics to battery management.

Back in psychology, the original home of reinforcement learning, progress in developing mathematical models powerful enough to be useful in engineering has been limited because of cultural problems between disciplines, similar to what held back reinforcement learning in general before 1987. However, a new path has opened up to connect neuropsychology with ADP which brings us closer to being able to truly understand the wiring and dynamics of the learning systems of the brain (Werbos and Davis 2016).

Mathematical Taxonomy of ADP Methods in General

There are many ways to classify the vast range of ADP tools and applications developed since 1990. Nevertheless, there are few if any ADP systems in use which do not fall into the sixfold classification given in White and Sofge (1992). Here, I will summarize these six types of ADP method and then mention extensions.

Heuristic Dynamic Programming (HDP)

HDP is the most direct method for approximating the Bellman equation, the foundation of exact dynamic programming. There are many legitimate ways to write that equation; one is:

$$J(\underline{x}(t)) = \max_{\underline{u}(t)} (U(\underline{x}(t), \underline{u}(t)) + \langle J(\underline{x}(t+1) / (1+r) \rangle) \quad (3)$$

where angle brackets denote the expectation value. When $\underline{x}$ is governed by a fully observable stochastic process (MDP), and when $r > 0$ or T is finite, it is well-known that a function J which solves this equation will exist. (See White and Sofge (1992) for the simple additional term needed to guarantee the existence of J for $r = 0$ and $T = \infty$, the case which some of us try to do justice to in our own decision-making.) To calculate the optimal policy of action, one tries to find an exact solution for this function J and then choose actions according to the (static)

optimization problem over $\underline{u}$ shown in Eq. 3. Because J may be any nonlinear function, in principle, early users would often try to develop a lookup table approximation to J , the size of which would grow exponentially with the number of possible states in the table.

The key idea in HDP is to model the function J in a parameterized way, just as one models stochastic processes when identifying their dynamics. That idea was developed in some detail in my 1987 paper in SMC, but was also described in many papers before that. The treatment in White and Sofge (1992) describes in general terms how to train or estimate the parameters or weights $\underline{W}$ in any model of J , $\hat{J}(\underline{R}(t), \underline{W})$, supplied by a user. A user who actually understands the dynamics of the plant well enough may choose to try different models of J and see how they perform. But the vast majority of applications today model J by use of a universal approximation function, such as a simple feedforward neural network. Andrew Barron has proven that the required complexity of such an approximation grows far more slowly, as the number of variables grows, than it would when more traditional linear approximation schemes such as lookup tables or Taylor series are used. Ilin, Kozma, and Werbos have shown that approximation is still better when an upgraded type of recurrent neural network is used instead; in the example of generalized maze navigation, a feedforward approximator such as a convolutional neural network simply does not work. In general, unless the model of J is a simple lookup table or linear model, the training requires the use of generalized backpropagation, which provides the required derivatives in exact closed form at minimum computational cost (White and Sofge 1992; Werbos 2005).

In his famous paper on $TD(\lambda)$ in 1987, Sutton proposed a generalization of HDP to include a kind of approximation quality factor λ which could be used to get convergence albeit to a less exact solution. I am not aware of cases where that particular approximation was useful or important, but with very tricky nonlinear decision problems,

it can be helpful to have a graded series of problems to allow convergence to an optimal solution of the problem of interest; see the discussion of “shaping” in White and Sofge (1992). There is a growing literature on “transfer learning” which provides ever more rigorous methods for transferring solutions from simpler problems to more difficult ones, but even a naive reuse of $\hat{J}(\mathbf{R}(t), \mathbf{W})$ and of π from one plant model to another is often a very effective strategy, as Jay Farrell showed long ago in aerospace control examples.

In getting full value from ADP, it helps to have a deep understanding of what the function $\hat{J}(\mathbf{R}(t), \mathbf{W})$ represents, across many disciplines (White and Sofge 1992; Lewis and Liu 2013). More and more, the world has come to call this function the “value function.” (This is something of a misnomer, however, as you will see in the discussion of Dual Heuristic Programming (DHP) below.) It is often denoted as “V” in computer science. It is often called a “Critic” in the engineering literature, following an early seminal paper by Widrow.

In control theory, Eq. 3 is often called the “Hamilton-Jacobi-Bellman” equation, because it is the stochastic generalization of the older Hamilton-Jacobi equation of enduring importance in fundamental physics. When control assumes no stochastic disturbance, it really is the older equation that one is solving. However, even in the deterministic cases, theorems like those of Barras require solution of the full Bellman equation (or at least the limit of it as noise goes to zero) in order to design a truly rigorous robust controller for the general nonlinear case. From that viewpoint, ADP is simply a useful toolbox to perform the calculations needed to implement nonlinear robust control in the general case.

Action-Dependent HDP (ADHDP), aka “Q Learning”

This family of ADP methods results from modeling a new value function J' (or “Q”) defined by:

$$J'(\underline{x}(t), \underline{u}(t)) = U(\underline{x}(t), \underline{u}(t)) + \gamma J(\underline{x}(t+1)) \quad (4)$$

One may develop a recurrence relation similar to (3) simply by substituting this into (3); the general method for estimating $\hat{J}'(\mathbf{R}(t), \mathbf{u}(t), \mathbf{W})$ is given in White and Sofge (1992), along with concrete practical applications from McDonnell Douglas in reconfigurable flight control and in low-cost mass production of carbon-carbon composite parts (a breakthrough important to the later development of the Dreamliner airplane after Boeing bought McDonnell Douglas and assimilated the technology). This type of value function has more complexity than the HDP value function, but its simplicity has value in some applications. One might argue that a truly general system like a brain would have an optimal hybrid of these two methods and more.

Dual Heuristic Programming (DHP, Dual HDP)

DHP uses yet another type of value function $\underline{\lambda}$ defined by:

$$\underline{\lambda}(\underline{x}(t)) = \nabla_{\underline{x}} J(\underline{x}(t)) \quad (5)$$

A convergent, consistent method for training this kind of value function is given in White and Sofge (1992), but many readers would find it useful to study the details and explanation by Balakrishnan and by Wunsch et al., reviewed in Lewis and Liu (2013). $\underline{\lambda}$ is a generalization of the dual variables well-known in economics, in operations research, and in control. The method given in White and Sofge (1992) is essentially a stochastic generalization of the Pontryagin equation. Because DHP entails a rich and detailed flow of feedback of values (plural) from one iteration to the next, it performs better in the face of more and more complexity, as discussed in theoretical terms in White and Sofge (1992) and shown concretely in simulation studies by Wunsch and Prokhorov reviewed in Lewis and Liu (2013). DHP value learning was the basis for Balakrishnan’s breakthrough in performance in hit-to-kill missile interception (Lewis and Liu

2013), which is possibly better known and understood in China than in the USA for political reasons.

Action-Dependent DHP and Globalized HDP

For reasons of length, I will not describe these three other groups discussed in White and Sofge (1992) in detail. The action-dependent version of DHP may have uses in training time-lagged recurrent networks in real time, and GDHP offers the highest performance and generality at the cost of some complexity. (In applications so far, DHP has performed as well. In the absence of noise, neural model predictive control (White and Sofge 1992) has also performed well and is sometimes considered as a (direct) type of reinforcement learning.)

Future Directions

Extensions to Spatial Complexity, Temporal Complexity, and Creativity

In the late 1990s, major extensions of ADP were designed and even patented to cope with much greater degrees of complexity, by adaptively making use of multiple time intervals and spatial structure (“chunking”) and by addressing the inescapable problem of local minima more effectively. See Werbos (2014) for a review of research steps needed to create systems which can cope with complexity as well as a mouse brain, for example. Realistically, however, the main challenge to ADP at present is to prove optimality under rigorous prior assumptions about “vector” plants (as in “vector intelligence”), considering systems which learn plants dynamics and optimal policy together in real time. It is possible that the more advanced systems may actually be dangerous if widely deployed before they are fully understood. It is amusing how movies like “Terminator 2” and “Terminator 3” may be understood as a (realistic) presentation of possible modes of instability in more complex nonlinear adaptive systems. In July 2014, the National Science Foundation of China and the relevant Dean at Tsinghua University asked me to propose

a major new joint research initiative based on Werbos (2014), with self-driving cars as a major testbed; however, the NSF of the USA responded at that time by terminating that activity.

Auctions

Bruce Hajek

University of Illinois, Urbana, IL, USA

Abstract

Auctions are procedures for selling one or more items to one or more bidders. Auctions induce games among the bidders, so notions of equilibrium from game theory can be applied to auctions. Auction theory aims to characterize and compare the equilibrium outcomes for different types of auctions. Combinatorial auctions arise when multiple-related items are sold simultaneously.

Keywords

Auction · Combinatorial auction · Game theory

Introduction

Three commonly used types of auctions for the sale of a single item are the following:

- *First price auction:* Each bidder submits a bid one of the bidders submitting the maximum bid wins, and the payment for the item is the maximum bid. (In this context “wins” means receives the item, no matter what the payment.)
- *Second price auction* or *Vickrey auction:* Each bidder submits a bid, one of the bidders submitting the maximum bid wins, and the payment for the item is the second highest bid.
- *English auction:* The price for the item increases continuously or in some small increments, and bidders drop out at some points in time. Once all but one of the bidders has dropped out, the remaining bidder wins and the payment is the price at which the last of the other bidders dropped out.

A key goal of the theory of auctions is to predict how the bidders will bid, and predict the resulting outcomes of the auction: which bidder is the winner and what is the payment. For example, a seller may be interested in the expected payment (seller revenue). A seller may have the option to choose one auction format over another and be interested in revenue comparisons. Another item of interest is efficiency or social welfare. For sale of a single item, the outcome is efficient if the item is sold to the bidder with the highest value for the item. The book of V. Krishna (2002) provides an excellent introduction to the theory of auctions.

Auctions Versus Seller Mechanisms

An important class of mechanisms within the theory of mechanism design are seller mechanisms, which implement the sale of one or more items to one or more bidders. Some authors would consider all such mechanisms to be auctions, but the definition of auctions is often more narrowly interpreted, with auctions being the subclass of seller mechanisms which do not depend on the fine details of the set of bidders. The rules of the three types of auction mentioned above do not depend on fine details of the bidders, such as the number of bidders or statistical information about how valuable the item is to particular bidders. In contrast, designing a procedure to sell an item to a known set of bidders under specific statistical assumptions about the bidders’ preferences in order to maximize the expected revenue (as in Myerson (1981)) would be considered a problem of mechanism design, which is outside the more narrowly defined scope of auctions. The narrower definition of auctions was championed by R. Wilson (1987). An article on ► [Mechanism Design](#) appears in this encyclopedia.

Equilibrium Strategies in Auctions

An auction induces a noncooperative game among the bidders, and a commonly used predictor of the outcome of the auction is an

equilibrium of the game, such as a Nash or Bayes-Nash equilibrium. For a risk neutral bidder i with value x_i for the item, if the bidder wins and the payment is M_i , the payoff of the bidder is $x_i - M_i$. If the bidder does not win, the payoff of the bidder is zero. If, instead, the bidder is risk averse with risk aversion measured by an increasing utility function u_i , the payoff of the bidder would be $u_i(x_i - M_i)$ if the bidder wins and $u_i(0)$ if the bidder does not win.

The second price auction format is characterized by simplicity of the bidding strategies. If bidder i knows the value x_i of the item to himself, then for the second price auction format, a weakly dominant strategy for the bidder is to truthfully report x_i as his bid for the item. Indeed, if y_i is the highest bid of the other bidders, the payoff of bidder i is $u_i(x_i - y_i)$ if he wins and $u_i(0)$ if he does not win. Thus, bidder i would prefer to win whenever $u_i(x_i - y_i) > u_i(0)$ and not win whenever $u_i(x_i - y_i) < u_i(0)$. That is precisely what happens if bidder i bids x_i , no matter what the bids of the other bidders are. That is, bidding x_i is a weakly dominant strategy for bidder i .

Nash equilibrium can be found for the other types of auctions under a model with incomplete information, in which the type of each bidder i is equal to the value of the object to the bidder and is modeled as a random variable X_i with a density function f_i supported by some interval $[a_i, b_i]$. A simple case is that the bidders are all risk neutral, the densities are all equal to some fixed density f , and the X_i 's are mutually independent. The English auction in this context is equivalent to the second price auction: in an English auction, dropping out when the price reaches his true value is a weakly dominant strategy for a bidder, and for the weakly dominant strategy equilibrium, the outcome of the auction is the same as for the second price auction. For the first price auction in this symmetric case, there exists a symmetric Bayesian equilibrium. It corresponds to all bidders using the bidding function β (so the bid of bidder i is $\beta(X_i)$), where β is given by $\beta(x) = E[Y_1 | Y_1 \leq x]$. The expected revenue to the seller in this case is $E[Y_1 | Y_1 < X_1]$, which is the same as the expected revenue for the second price auction and English auction.

Equilibrium for Auctions with Interdependent Valuations

Seminal work of Milgrom and Weber (1982) addresses the performance of the above three auction formats in case the bidders do not know the value of the item, but each bidder i has a private signal X_i about the value V_i of the item to bidder i . The values and signals $(X_1, \dots, X_n, V_1, \dots, V_n)$ can be interdependent. Under the assumption of invariance of the joint distribution of $(X_1, \dots, X_n, V_1, \dots, V_n)$ under permutation of the bidders and a strong form of positive correlation of the random variables $(X_1, \dots, X_n, V_1, \dots, V_n)$ (see Milgrom and Weber 1982 or Krishna 2002 for details), a symmetric Bayes-Nash equilibrium is identified for each of the three auction formats mentioned above, and the expected revenues for the three auction formats are shown to satisfy the ordering $R^{(\text{first price})} \leq R^{(\text{second price})} \leq R^{(\text{English})}$. A significant extension of the theory of Milgrom and Weber due to DeMarzo et al. (2005) is the theory of security-bid auctions in which bidders compete to buy an asset and the final payment is determined by a contract involving the value of the asset as revealed after the auction.

Combinatorial Auctions

Combinatorial auctions implement the simultaneous sale of multiple items. A simple version is the simultaneous ascending price auction with activity constraints (Cramton 2006; Milgrom 2004). Such an auction procedure was originally proposed by Preston, McAfee, Paul Milgrom, and Robert Wilson for the US FCC wireless spectrum auction in 1994 and was used for the vast majority of spectrum auctions worldwide since then Cramton (2013). The auction proceeds in rounds. In each round a minimum price is set for each item, with the minimum prices for the initial round being reserve prices set by the seller. A given bidder may place a bid on an item in a given round such that the bid is greater than or equal to the minimum price for the item. If one or more bidders bid on an item in a round, a provi-

sional winner of the item is selected from among the bidders with the highest bid for the item in the round, with the new provisional price being the highest bid. The minimum price for the item is increased 10 % (or some other small percentage) above the new provisional price. Once there is a round with no bids, the set of provisional winners is identified. Often constraints are placed on the bidders in the form of *activity rules*. An activity rule requires a bidder to maintain a history of bidding in order to continue bidding, so as to prevent bidders from not bidding in early rounds and bidding aggressively in later rounds. The motivation for activity rules is to promote *price discovery* to help bidders select the packages (or bundles) of items most suitable for them to buy. A key is that complementarities may exist among the items for a given bidder. Complementarity means that a bidder may place a significantly higher value on a bundle of items than the sum of values the bidder would place on the items individually. Complementarities lead to the *exposure problem*, which occurs when a bidder wins only a subset of items of a desired bundle at a price which is significantly higher than the value of the subset to the bidder. For example, a customer might place a high value on a particular pair of shoes, but little value on a single shoe alone.

A variation of simultaneous ascending price auctions for combinatorial auctions is auctions with package bidding (see, e.g., Ausubel and Milgrom 2002; Cramton 2013). A bidder will either win a package of items he bid for or no items, thereby eliminating the exposure problem. For example, in simultaneous clock auctions with package bidding, the price for each item increases according to a fixed schedule (the clock), and bidders report the packages of items they would prefer to purchase for the given prices. The price for a given item stops increasing when the number of bidders for that item drops to zero or one, and the clock phase of the auction is complete when the number of bidders for every item is zero or one. Following the clock phase, bidders can submit additional bids for packages of items. With the inputs from bidders acquired during the clock phase and supplemental bid phase, the auctioneer then runs a winner determination algorithm to

select a set of bids for non-overlapping packages that maximizes the sum of the bids. This winner determination problem is NP hard, but is computationally feasible using integer programming or dynamic programming methods for moderate numbers of items (perhaps up to 30). In addition, the vector of payments charged to the winners is determined by a two-step process. First, the (generalized) Vickrey price for each bidder is determined, which is defined to be the minimum the bidder would have had to bid in order to be a winner. Secondly, the vector of Vickrey prices is projected onto the core of the reported prices. The second step insures that no coalition consisting of a set of bidders and the seller can achieve a higher sum of payoffs (calculated using the bids received) for some different selection of winners than the coalition received under the outcome of the auction. While this is a promising family of auctions, the projection to the core introduces some incentive for bidders to deviate from truthful reporting, and much remains to be understood about such auctions.

Summary and Future Directions

Auction theory provides a good understanding of the outcomes of the standard auctions for the sale of a single item. Recently emerging auctions, such as for the generation and consumption of electrical power, and for selection of online advertisements, are challenging to analyze and comprise a direction for future research. Much remains to be understood in the theory of combinatorial auctions, such as the degree of incentive compatibility offered by core projecting auctions.

anesthetic drug mechanisms, the large inter-patient variability, and the difficulty in sensing the responses to anesthetic drugs. Following a brief introduction to general anesthesia, those challenges will be reviewed from a control engineering perspective. Recent advances in the understanding of the neurobiology of anesthesia and developments in sensing and monitoring have resulted in renewed interest in automatic control of anesthesia. These developments will be discussed, followed by a review of recent research in control of depth of anesthesia, as well as analgesia. The appropriateness of various control methodologies for this problem will also be discussed.

Abstract

In many fields of human endeavor, ranging from the mundane such as DVD players to the technologically advanced such as space flight, control systems have become ubiquitous, to the point that control technology has been termed by Karl Astrom the “hidden technology.” However, in the field of anesthesia, despite efforts going back to 1950, closed-loop control is rarely used to automate the delivery of drugs to safely achieve and maintain a desired clinical anesthetic effect. This might be because of the complexity of physiological systems, the poor understanding of

Introduction

Anesthesia drug delivery involves the continuous administration of a combination of potentially dangerous drugs with frequent adjustments in order to induce a temporary loss of consciousness and memory while maintaining normal vital cardiorespiratory function during surgical stimulation. Over the last two decades, advances in central and autonomous nervous system monitoring technology have yielded a new set of real-time monitors and sensors to capture the effect of these drugs on the patient. As a result, automated feedback control of anesthetic drug delivery to a pre-defined state can be a means of providing the patient with a titration specifically adjusted to his or her needs. Although the idea of automated anesthetic drug delivery has been investigated for over 50 years, and despite rapid progress over the last 10 years, no real clinical breakthrough has yet been achieved and it has yet to become standard of care. In this entry, drawing from Dumont (2012), we attempt to give an overview of the current state of the art in the field.

Overview of Anesthesia

The goals of anesthesia are to allow the surgeon to operate in optimal conditions while (i) protecting the patient from the detrimental effects of the surgical procedure and (ii) maintaining homeostasis and hemodynamic stability as much as it is possible. For this, the anesthesiologist administers a number of drugs to the patients: hypnotics that act primarily on the brain to induce unconsciousness (also known as hypnotic state) in the patient so as to prevent intraoperative awareness and memorization; analgesics to suppress nociceptive reactions in presence of painful stimulus; and in some surgeries neuromuscular blocking agents to induce paralysis in order to suppress reflex muscle activity. The role of the anesthesiologist is to carefully dose the amount of drugs to avoid underdosing which can lead to intraoperative awareness and possible postoperative post-traumatic stress as well as overdosing which, due to the toxicity of the drugs involved, may lead to serious or even fatal intra- or postoperative consequences for the patient.

There are two broad classes of anesthetic agents: inhaled agents and intravenous agents. Modern inhaled anesthetics have a combined hypnotic and minor analgesic effect (and limited neuromuscular blocking action) and limited hypotensive action. An advantage of inhaled anesthetics is that measuring the difference between inhaled and exhaled concentrations allows an accurate estimation of plasma or brain drug uptake. Modern total intravenous anesthesia (TIVA) usually involves propofol as hypnotic agent and remifentanyl as analgesic agent. Propofol is characterized by fast redistribution and metabolism, provides rapid emergence, and has good anti-emetic properties. Remifentanyl is characterized by a very rapid onset and brevity of action, thus minimizing undesirable opioid-induced side effects. Together with the high specificity of both agents, this makes them ideal for control of anesthesia. Hence, the vast majority of studies of closed-loop control of anesthesia have been performed using TIVA based on propofol and remifentanyl.

We can divide the anesthesia procedure into three distinct stages: induction, maintenance, and emergence.

Induction Induction is the phase during which the patient goes from consciousness to unconsciousness and although quite short is critical to the overall safety of the procedure. As soon as the patient loses consciousness, he or she will usually stop breathing and need to be rapidly intubated to allow for artificial ventilation. To facilitate insertion of the endotracheal tube, the bolus of propofol is usually preceded by a bolus of opioid such as remifentanyl. Furthermore, in some situations, as soon as the patient loses consciousness, a NMB is administered, to optimize intubation conditions and blunt any reflex during intubation. Overdosing of the patient at induction may lead to severe hypotension which will need to be corrected with vasopressors and may place elderly or fragile patients into too deep an hypnotic state which may lead to prolonged periods of electrocortical silence, thought to have harmful long-term effects. Minimizing the amount of overshoot at induction is thus critical.

Maintenance After induction, it is necessary to maintain an adequate level of unconsciousness and to blunt nociceptive reactions. When using inhaled anesthetics, the measurement of the end-tidal vapor concentration provides the anesthesiologist with a reliable feedback quantity. The situation is more complex with TIVA, as there is no reliable method to provide arterial concentration of propofol or remifentanyl. In the absence of brain monitoring, the anesthesiologist will typically use hemodynamic parameters such as heart rate and blood pressure for guidance, or watch out for patient movement. The development of TIVA has been made easier through the development of pharmacokinetic model-driven infusion devices. These devices reach a desired plasma (or effect site) theoretical concentration by using a computer-controlled infusion pump driven by the pharmacokinetic parameters of the drug. The resulting target-controlled infusion (TCI) (Absalom and Struys 2007) anesthesia is used exten-

sively in most of the developed world except in the USA where it has not been approved by the FDA.

Emergence The emergence from anesthesia is simply achieved by turning off delivery of the hypnotic and analgesic agents used during the surgery. This is usually done during skin closure so that the patient wakes up faster at the end of the surgery. An additional bolus of a long-acting opioid may be given for postoperative pain management. Extubation takes place as soon as the patient shows clinical signs of wakefulness.

Sensing for Anesthesia

In this section, we will focus on sensing for the three major components of anesthesia, hypnosis, nociception, and muscular relaxation. This is above and beyond the monitoring of standard physiological parameters such as heart rate, respiratory rate, minute ventilation, airway pressure, end-tidal CO_2 through capnography, blood pressure (either noninvasive or through an arterial line), and oxygen saturation via pulse oximetry.

Sensing for Hypnosis

The effects of anesthetic drugs on the electroencephalogram (EEG) have been known since the early 1940s when neurophysiologists observed that the EEG of anesthetized patients contained slower waves with higher amplitudes. However, raw EEG is difficult to detect and interpret in real time, and thus a number of techniques have been used to extract univariate features from the EEG to quantify the hypnotic component of anesthesia. Two such features of historical interest are the median frequency (MEF) and the spectral edge frequency (SEF), i.e., the frequency up to which 95% of the EEG power is present. However, this is not until the advent of the BISTM monitor that EEG has become more commonplace. The BIS monitor is based on the observation that with increasing anesthetic depth, EEG frequencies tend to synchronize. This leads to the use of the bispectrum to characterize phase coupling of different frequencies, Sigl and Chamoun (1994).

The BISTM monitor combines a number of bispectra, bicoherence indices, and power spectral values to derive a [0–100] index known as depth of hypnosis (DoH). An index of 100 represents the awake state, while it decreases with increasing concentration of anesthetics. General anesthesia is obtained for an index between 60 and 40. Lower values represent deep hypnotic states and usually are not desirable. Introduced in the mid-1990s, the BIS monitor largely dominates the market for DoH monitors.

Another DoH monitor is the M-EntropyTM monitor, introduced in 2003, (Viertio-Oja et al. 2004) which provides two indices, the State Entropy (SE), a measure of the irregularity of frontal electroencephalogram activity within the frequency range of 0.8–32 Hz, and the Response Entropy (RE), a measure of the irregularity of frontal electroencephalogram activity within the frequency range of 0.8–47 Hz. While SE is a surrogate of the BIS, the difference between RE and SE is thought of as an indication of nociception because it may contain some facial EMG.

Although it provides anesthesiologists with a reliable index of hypnosis, the BIS monitor introduces a large and variable delay; is inherently nonlinear, tending to evolve in a stepwise manner during transient phases of anesthesia; and is essentially a black box hard to characterize for control design purposes. On the other hand, the M-Entropy responds much faster, is a simpler algorithm, but tends to provide a very noisy index.

The more recent NeuroSenseTM monitor that addresses these concerns was developed specifically for use in closed-loop control of anesthesia. It derives a bilateral index based on wavelet decomposition of a frontal EEG, with emphasis on the γ -band activity, Zikov et al. (2006). It has been shown to relate well to the BIS in steady state, but possesses much faster, delay-free, and constant dynamics over its entire range, Bibian et al. (2011).

Sensing for Nociception

Clinical monitoring of nociception or antinociception is based on capturing the response

of the autonomic nervous system (ANS) to a noxious stimulus. For example, heart rate and blood pressure both tend to increase sharply in case of a sympathetic response to a non-properly blunted noxious stimulus. This is, for instance, the basis for the AnalgoscoreTM, a pain score derived from heart rate (HR) and mean arterial pressure (MAP) that has been used in closed-loop control, Hemmerling et al. (2009). The GE's Surgical Pleth Index (SPITM), first introduced as the Surgical Stress Index (SSI), is computed from finger photoplethysmographic (PPG) waveform amplitudes and pulse-to-pulse intervals, Wennervirta et al. (2008). The ANITM monitor analyzes the tachogram with wavelets and tracks the time-varying power in the high-frequency band. It has been shown to respond to the administration of anesthetic drugs and to nociceptive stimuli (Jeanne et al. 2009). A related technique is based on wavelet-based cardiorespiratory coherence, resulting in a normalized index that has been shown to respond to both nociceptive and anti-nociceptive events, Brouse et al. (2010). The NOLTM index by Medasense uses machine learning to derive an index from features of the PPG, heart rate variability (HRV), skin conductance, movement, and temperature; see Ledowski (2019) for more on nociception monitoring.

An interesting method for assessing nociceptive reactions is based on the observation that a sudden electrocortical activation, e.g., demonstrated by an increase in exDoH values, is a reflection of an inadequate analgesic state. This principle has been used in the most clinically tested closed-loop controller for anesthesia, Liu et al. (2011).

Modelling for Anesthesia

Modelling of the distribution and effect of anesthetic drugs has traditionally been done using pharmacokinetic (PK) models for the former and pharmacodynamic (PD) models for the latter. Typically, pharmacokinetic models are based on compartmental models, while PD models consist of a simple compartment followed by a sigmoidal

nonlinearity. For propofol, a three-compartment is used, yielding the transfer function between the infusion rate I_p and the plasma concentration C_p :

$$C_p = \frac{1}{V_1} \frac{(s + z_1)(s + z_2)}{(s + p_1)(s + p_2)(s + p_3)} I_p(s)$$

The PD model is usually described by a transfer function between the plasma concentration C_p and the effect site concentration C_e

$$C_e(s) = \frac{k_{e0}}{s + k_{e0}} C_p(s)$$

followed by a Hill equation relating C_e to the effect:

$$E(C_e) = \frac{C_e^\gamma}{EC_{50}^\gamma + C_e^\gamma}$$

where EC_{50} denotes the effect site concentration corresponding to a 50% clinical effect and γ is the cooperativity coefficient. For remifentanyl, most PK models involve only two compartments, resulting in a simpler transfer function (Fig. 1).

Propofol and remifentanyl are known to interact with each other in a synergistic fashion in their hypnotic/analgesic effect (Kern et al. 2004). This observation constitutes the basic assumption on which the concept of balanced anesthesia is based. Static pharmacodynamic interactions between these two drugs have been studied using the concept of isoboles reflecting, e.g., the probability of response to painful stimuli through the use of response surfaces, as:

$$E(v_p, v_r) = \frac{(v_p + v + r + \alpha v_p v_r)^\gamma}{(v_p + v + r + \alpha v_p v_r)^\gamma + 1}$$

where v_p and v_r are, respectively, the effect site concentrations of propofol and remifentanyl normalized by their EC_{50} , and $\alpha > 0$ characterizes the synergy between the two drugs. Note that the interaction is equivalent to the use of a new fictitious drug $v = v_p + v_r + \alpha v_p v_r$.

While pharmacokinetic and dynamicists strive to improve the accuracy of PKPD models with the introduction of a number of covariates in an attempt to reduce the uncertainty in TCI systems, a number of studies have shown that in

Automated Anesthesia Systems, Fig. 1 A three-compartment PK model

order to develop a clinically satisfactory closed-loop control systems, simpler models such as first-order plus delay may have the same level of predictive power.

Control of Anesthesia

Control Paradigm

After ensuring a fast and safe induction, the anesthesiologist needs to maintain the patient in an adequate state of hypnosis and analgesia by adjusting the anesthetic and opioid titration rates in order to avoid both under- and overdosing of the patient. An automated system that would regulate drug dosing to maintain the adequacy of the anesthetic regimen could reduce the anesthesiologist's workload. Closed-loop anesthesia is not meant to replace the anesthesiologist, but to allow them to concentrate on higher-level tasks focusing on the well-being of the patient.

A closed-loop controller for anesthesia should induce the patient rapidly, but with minimal overshoot, and then maintain the patient in an adequate state of anesthesia and analgesia at least as well as an expert anesthesiologist. Translating this in control specifications is difficult, but for a DoH index, it could be translated into a rise time at induction of 3–4 min, with overshoot less than 10–15% and a good damping ratio of at least 0.7. During maintenance the DoH index should stay about 85% of the time within 10 points of the target. Control of analgesia should be such that in case of arousal (which in control engineering

terms can be thought of as an output disturbance), the patient response is rapidly suppressed, say within 2 min and without inducing oscillations. The clinical outcome should be improved hemodynamic stability, faster emergence, and possibly reduced drug consumption. The main challenge is the inherent variability, both interpatient and intraoperative; thus, robust stability and performance are paramount.

Historical Period

The first efforts to automate anesthesia go back to the work of Mayo and Bickford in the early 1950s with their attempts to develop EEG-based automatic delivery of volatile agents, see, e.g., Bickford (1950). What follows is by no means an exhaustive review of the published work on closed-loop control of anesthesia. Closer to us, in the 1980s a significant amount of work was performed on end-tidal concentration control for inhaled anesthetics such as halothane (see, e.g., Westenskow et al. 1986); closed-loop control of neuromuscular blockade (see, e.g., Brown et al. 1980); or mean arterial pressure control (Monk et al. 1989). In 1989, Schwilden (Schwilden et al. 1989) published the first work on closed-loop delivery of propofol guided by the EEG median frequency. during a study on 11 healthy volunteers. For a review of the progress from 1949 to 1980, see Chilcoat (1980).

The Modern Period

The advent of the BIS DoH monitor in the mid-1990s resulted in a significant increase in the

number of both simulated and clinical studies on closed-loop control of anesthesia, focusing on DoH.

An early effort by an engineering group was the development of DoH control during isoflurane anesthesia and its clinical testing on human volunteers during minor surgical procedures, Gentilini et al. (2001b). The system consisted of two cascaded loops, the slave one being in charge of isoflurane end-tidal concentration at a setpoint given by the master loop in charge of maintaining the BIS DoH index between 40 and 50. Both controllers were model-based internal model controllers (IMC). The system behaved satisfactorily during clinical tests. The patients, however, were induced manually, the controllers taking over only for the maintenance phase. That group also considered control of mean arterial pressure by closed-loop control of alfentanil using a PKPD model-based explicit predictive controller with constraints, Gentilini et al. (2002). These two systems were then combined for joint control of hypnosis and analgesia during successful clinical tests, Gentilini et al. (2001a).

Early efforts at BIS-guided closed-loop control of propofol infusion were performed by Absalom et al. (2002) and Absalom and Kenny (2003) who used a PID controller tuned in a very ad hoc manner to adjust the propofol effect site concentration target of a TCI system. In clinical tests on 20 patients, the performance varied significantly from patient to patient, the system displaying instability for some of the patients. All patients were induced under TCI mode, with an effect site concentration chosen by the clinician who then switched to closed-loop control for the maintenance phase. A system with a similar structure is described in Liu et al. (2006), using a rule-based controller that is very similar to a PD controller. After significant tuning, this system was tested against manual control in a randomized controlled trial involving 164 patients (83 in closed-loop). That system was shown to outperform manual control in terms of BIS variability and resulted in similar hemodynamic stability. Puri et al. (2007) describes a heuristically tuned “adaptive” PID

controller tested against manual control in a clinical trial involving 40 subjects. A similar system is described in Hemmerling et al. (2010) which tests a heuristic set of rules emulating a PD controller against manual control in a clinical trial involving 40 subjects. Both studies report similar results but lack a detailed description of the control algorithms. In Liu et al. (2011), a system that manipulates both the propofol and remifentanyl infusion rates based on the BIS alone is presented. The basic idea is that sudden increases in the BIS index are due to a nociceptive reaction and reflect an inadequate analgesic state. The controller that manipulates the remifentanyl is a combination of a proportional action and a number of heuristic rules. Randomized clinical trials involving 167 patients on a wide variety of procedures showed that the system provides better control of the BIS than manual control and similar hemodynamic stability accompanied with increased remifentanyl consumption. This system, like its predecessor, induces the patient in TCI mode, with manually set targets for both propofol and remifentanyl effect site concentrations.

Because the above systems were designed heuristically, their theoretical properties are difficult, if not impossible to assess. A rigorous approach to robust PID tuning for anesthesia is described in Dumont et al. (2009) where a PID controller is robustly tuned for a population of 44 adult patients. Results of a feasibility study in adults showed that this simple controller provided adequate anesthesia (Dumont et al. 2011). This led to the development of a similar system for pediatric use (van Heusden et al. 2014; West et al. 2013), whose results in a clinical study indicate that a robust PID controller provides clinically satisfactory performance despite the significant interpatient uncertainty in that pediatric population. An extension of this system that manipulates both propofol and remifentanyl infusion rates based only on the DoH index was developed using a modified habituating control framework (van Heusden et al. 2018) and successfully tested on 127 patients undergoing surgical procedures (West et al. 2018). An important feature of that system is its safety system

Automated Anesthesia Systems, Fig. 3 Example of closed-loop control of anesthesia for a 220 min procedure for a 37-year-old patient. The top pane shows the evolution of the depth of hypnosis (red trace) as well as the EMG signal (green trace). At induction, the DoH drops to about 50, which is the setpoint aimed for during maintenance. It then goes back up at emergence, a few minutes after and of drug infusion. The middle pane shows the infusion for propofol (yellow) and remifentanyl (blue). The bottom pane shows the corresponding theoretical plasma concentrations for propofol and remifentanyl

loop control of anesthesia, the regulatory hurdles abound before it can be approved for routine clinical use (Manberg et al. 2008). The US FDA has made it clear that these systems will have to be based on sound and verifiable control theory and that it will require guarantees in terms of stability, robustness, and performance. For the technology to mature and become clinical reality, close cooperation between control engineers, clinicians, medical device manufacturers, and regulatory bodies will be required.

It is also important to realize that the systems discussed here only consider a subset of what an anesthesiologist needs to do to ensure patient safety. Other systems, e.g., for hemodynamics and fluid management, are under development, and some are even undergoing clinical trials. Some clinical trials combining DoH closed-loop control together with hemodynamic (blood pressure) control and automated fluid management have recently taken place.

For those systems to be adopted clinically, their benefits in terms of improved patient outcomes will have to be clearly demonstrated, and this will necessitate large and costly multicenter clinical studies involving tens of thousands of patients.

Automated Insulin Dosing for Type 1 Diabetes

B. Wayne Bequette

Chemical and Biological Engineering,

Rensselaer Polytechnic Institute, Troy, NY, USA

Abstract

The development of automated insulin delivery (also known as a closed-loop artificial

pancreas) systems has been an active research area since the 1960s, with an intense focus since 2005. In the United States in 2019, there is currently one commercial device available, with others under development. There is also a strong do-it-yourself community of individuals developing and using closed-loop technology. In this chapter we provide an overview of the challenges in developing automated insulin delivery systems and the algorithms that are commonly used to regulate blood glucose.

Keywords

Biomedical control · Drug infusion · Fault detection · Clinical trials

Introduction

The beta and alpha cells of the pancreas secrete insulin and glucagon, respectively, to regulate blood glucose (BG) concentrations; insulin decreases BG, while glucagon increases BG. The pancreas of an individual with type 1 diabetes no longer produces these hormones, so they must take insulin (by injection, or using continuous insulin infusion pumps) to survive. This is in contrast to people with type 2 diabetes, who have a pancreas that produces insulin but not enough to adequately regulate their BG. People with type 2 diabetes (90–95% of the diabetes population) often regulate BG through diet, exercise, and oral medications. The focus of this chapter is on automated insulin dosing (AID) systems for people with type 1 diabetes.

Before the discovery by Banting and Best that insulin was the hormone that regulated blood glucose in 1921, anyone diagnosed with diabetes was doomed to a short life; for an overview of the history of the development and use of insulin, see Hirsch (2004). For many decades someone with type 1 diabetes survived with multiple daily injections of insulin, but without real feedback. By the 1940s urine could be tested for glucose concentration, but easy-to-use urine strips were not available until the 1960s. Blood glucose

test meters were not widely available for home use by an individual until the 1980s. Finally, blood glucose control was not recognized to be important until results of the Diabetes Control and Complications Trial (DCCT) were published in 1993. For many people today the state of the art remains multiple daily injections of insulin (one long-acting shot in the morning, followed by injections of rapid-acting insulin at mealtime, or to correct for high blood glucose) and multiple finger-stick measurements of blood glucose using self-monitoring blood glucose (SMBG) meters – ideally before bedtime, when awakening, at each meal, and before potentially dangerous activities such as driving.

The use of insulin pumps became more common in the late 1990s; these pumps are operated “open-loop” with specified rates of insulin delivery, using rapid-acting insulin. Continuous glucose monitors (CGM), which provide a measurement of the interstitial fluid (just underneath the skin) glucose at frequent intervals, typically every 5 min, have been widely available for less than 15 years. These insulin pumps and CGMs are absolutely critical components of a closed-loop automated insulin dosing (artificial pancreas) system. Note that the CGM signal is related to blood glucose (BG) but will often lag the actual BG, may be biased, will have some uncertainty, and could suffer from signal attenuation or dropout. Devices for a closed-loop system are shown in Fig. 1.

To begin our discussion, it is helpful to understand common units and orders of magnitude. In the United States, blood glucose is measured in mg/dl. A healthy individual (without diabetes) will typically have a fasting BG level of 80–90 mg/dl, with brief excursions to 125–150 mg/dl due to meals. An individual with type 1 diabetes can drift to over 400 mg/dl (hyperglycemia) if insufficient insulin is given and yet be in danger of going below 70 mg/dl (hypoglycemia) if too much insulin is given. The common quantity of insulin is international units, which we will refer to as units (U) of insulin throughout this chapter. An individual with type 1 diabetes may have a basal (steady-state) insulin infusion rate of 1 U/h, or 24 U/day, but inject another 24 U of insulin

Automated Insulin Dosing for Type 1 Diabetes, Fig. 1

Components of a closed-loop automated insulin delivery (IAD) system: CGM (sensor), pump and infusion set, smartphone or other receiver with a control interface and containing the control algorithm and other logic. The number of devices can be reduced by putting the control algorithm and interface directly on the insulin pump

throughout the day to compensate for meals. A population range might be 0.5–3 U/h basal (12–72 U/day), with another 12–72 U/day for meals (while a 50-50 split of basal-meal insulin is a rule of thumb, this can vary significantly from person to person). An individual will typically require one U of insulin for each 10–15 g carbohydrates consumed in a meal. Individuals will also make use of a correction or insulin sensitivity factor to decide how much insulin to give to reduce their blood glucose levels. Typically, 1 U of insulin will reduce BG by 40–80 mg/dL; while time is not explicitly mentioned in these factors, it will typically take 2 h to reduce the BG. Also notice that, since a bolus (injection) of insulin is a pulse input, the fact that a new pseudo steady-state in BG occurs is indicative of an integrating process, at least for the short time scale. On a longer time scale, however, there is a one-to-one relationship between the insulin basal rate (U/h) and BG (mg/dl).

The focus of this discussion has been on insulin, because there is no current glucagon formulation that is stable for long periods of time at body temperature. If someone needs to raise their BG, they will consume carbohydrates; currently glucagon is used to rescue someone who passed out or is in a coma and cannot eat – a glucagon solution is quickly mixed and injected when needed. Stable forms of glucagon are under

development, and glucagon has been used in some clinical studies as noted below.

Challenges

There are multiple challenges to individuals regulating BG. Insulin delivered subcutaneously takes a long time to act to decrease the BG. While the pancreas of a healthy individual has a peak in insulin action less than 5 min after a “glucose challenge,” insulin delivered subcutaneously has a peak action of roughly 75 min and continues to act for 4–8 h. Thus, an individual must realize that insulin given 2 h ago may have 50% of the insulin effect remaining. Current insulin pumps allow individuals to keep track of “insulin on board” (IOB), an estimation of the amount of insulin remaining to act. Bequette (2009) reviews the research protocols used to develop pharmacodynamics models and to calculate IOB.

Meals and exercise represent the greatest “disturbances” to regulating BG. The dynamic impact of a meal varies tremendously with meal content – a glass of orange juice can have a rapid effect on BG (and is often taken if an individual is becoming hypoglycemic), while a high-fat meal has an effect that extends over several hours. A meal also requires a significant amount of insulin to compensate for the carbohydrates in the meal.

An individual with a basal insulin requirement of 1 U/h and a carb-to-insulin ratio of 10 g/U might need 7.5 U of insulin to cover a 75 g carbohydrate meal. Thus, the amount of insulin given for the meal is equivalent to 7.5 h worth of basal insulin. It would be rare for any manufacturing process to have this type of rangeability in an actuator!

Aerobic exercise can cause a relatively rapid decrease in BG and lead to reduced insulin needs for several hours, while anaerobic activity may result in a short-term increase in BG. An individual with type 1 diabetes walks a tightrope between under-delivery of insulin, which can lead to high blood glucose (hyperglycemia) and over-delivery of insulin, which can lead to low blood glucose (hypoglycemia). The risks of hyperglycemia are generally long-term in that higher mean glucose levels are correlated with micro- and macrovascular diseases and retinopathy. The risks of hypoglycemia, on the other hand, are largely short-term, such as drowsiness and, in a worst-case scenario, a diabetic coma leading possibly to death.

Overnight hyperglycemia is perhaps the greatest fear of a parent of a child with type 1 diabetes; it is common for a parent to check blood glucose at around 1 am or so. This fear often causes people to under-deliver insulin overnight, which can lead to hyperglycemia and long-term consequences. CGMs that provided alarms to awake individuals, or their parents, were not as effective as expected, partially due to a relatively high false positive rate for the devices at that time (the early 2000s); these problems were noted by Buckingham et al. (2005). These challenges motivated the development of initial closed-loop systems, in the form of low-glucose suspend algorithms, which shut off an insulin pump to avoid hypoglycemia, with a focus on overnight applications.

A number of faults can occur with sensors and insulin infusion sets. CGM signals can attenuate due to a person putting pressure on the sensor. Also, Bluetooth or other signals between the devices can drop out. Infusion sets are normally worn for 3 days before replacement, but these sets can fail in less time, sometimes immediately after insertion. Bequette (2014) provides an overview of these problems and possible fault detection techniques.

Control Algorithms and Objectives

Four types of algorithms have typically been used to regulate glucose by manipulating insulin infusion: (i) on-off, (ii) fuzzy logic/expert systems, (iii) proportional-integral-derivative (PID), and (iv) model predictive control (MPC). The control objectives are often either to control to a specific set point or to control to a desired range of glucose; the set point or range can vary with time of day. An overview of the different algorithms is provided by Bequette (2012).

Early closed-loop research focused on overnight control of blood glucose using a simple on-off algorithm, that is, if the glucose reached a hyperglycemic threshold, then the pump was shut off (low-glucose suspend) for a period of time. The next advance was to develop a predictive low-glucose suspend (PLGS) algorithm to shut off the pump if the CGM was predicted to go low during a future prediction horizon (often 30 min) (Buckingham et al. 2010; Cameron et al. 2012a).

A fuzzy logic-based strategy, based on the CGM, its rate of change, and acceleration, is used by Mauseth et al. (2010). The MD-Logic system by Atlas et al. (2010) uses a combination of set point and control-to-range concepts.

The proportional-integral-derivative (PID) controller is ubiquitous in chemical process applications. Steil et al. (2011) proposed a PID controller with a model-based insulin feedback term, making it similar to a cascade control strategy; an analysis of this approach is provided by Palerm (2011). The model-based insulin feedback plays a similar role to IOB since high model-predicted insulin predictions correspond to a high IOB.

Model predictive control (MPC) uses a model to forecast the effect of proposed insulin infusion rates on glucose over a prediction horizon. The majority of proposed AID algorithms are based on MPC. Objectives include tracking a BG set point (which could be changing with time), keeping BG within a desired range (Zone-MPC or control to range) (Kovatchev et al. 2009b; Grosman et al. 2010), or minimizing risk. Cameron et al. (2012b) develop a multiple model probabilistic predictive control (MMPPC)

strategy that accounts for uncertainty in predictions and manipulates insulin to minimize hypoglycemic risk.

In a simulation-based study, Cameron et al. (2011) compare basal-bolus, PID, MPC, and an enhanced MPC algorithm based on risk management. The merits of PID and MPC were analyzed by Steil (2013) and Bequette (2013), respectively. An overview of the different algorithms, delivery methods, and other engineering decisions is provided by Doyle et al. (2014). Much of the effort has involved the use of a single hormone, but a number of two-hormone (insulin and glucagon) studies have been performed.

Most algorithms require that a meal be “announced” to provide feedforward control through the associated meal insulin bolus; this requires the individual to estimate the carbohydrates in their meals and provide this information to the “hybrid” controller (the term commonly used for the combination of feedforward and feedback control). The MMPPC approach of Cameron et al. (2012b, 2014) also anticipates and detects meals, reducing the burden on individuals to provide a meal announcement and insulin bolus at mealtime.

Exercise can rapidly decrease BG and increase insulin sensitivity (reducing the insulin required) for many hours; thus it is desirable to provide exercise information as part of an AID strategy. Stenerson et al. (2014) incorporate heart rate and an accelerometer into a PLGS system but find little additional benefit due to the use of heart rate. Turksoy et al. (2015) use energy expenditure and galvanic skin resistance as additional sensor inputs to improve BG control during exercise. Breton et al. (2014) add heart rate to a control-to-range MPC strategy to improve BG regulation during exercise.

Fault Detection

Possible component-related faults include loss of the sensor signal (due to Bluetooth dropouts), pressure-induced sensor attenuation (PISA, due to pressure on the sensor), partial or complete insulin infusion set failure, and loss of controller

(smart phone battery depletion). Baysal et al. (2014) present an approach to detect PISAs based on signal characteristics such as rate of change. Howsmon et al. (2017, 2018) present a statistical process monitoring type of approach to detect insulin infusion rate failures. Most systems default to a pre-programmed basal insulin delivery rate upon loss of communication of 20 min or more.

Simulation Models

There are two commonly used models to simulate the response of blood glucose to subcutaneous insulin infusion and meal carbohydrates. Kovatchev et al. (2009a) discuss the use of a simulator that has been accepted by the FDA to demonstrate preliminary results that can be used in investigational device exemption (IDE) applications for clinical trial studies. Wilinska et al. (2010) present a simulation framework based on the model developed by Hovorka et al. (2004).

The Hovorka simulation model is used to illustrate the effects of insulin and carbohydrates on BG. Figure 2 compares the effect of basal insulin rate on the steady-state BG for three different insulin sensitivities (nominal $\pm$ 20%). Notice that even with a fixed sensitivity a relatively small change in insulin basal rate has a large effect on the steady-state BG. Also, insulin sensitivity varies with time of day and with exercise and illness. In this example, the nominal sensitivity curve with a basal rate of 1.058 U/h yields a steady-state BG of 120 mg/dL. If the actual sensitivity is 20% less, the BG is 190 mg/dL, while if the sensitivity is 20% more, the BG is 75 mg/dL. An individual that struggles with hypoglycemia is likely to err on the side of a lower basal insulin rate. Figure 3 is an open-loop simulation for a 50 g carbohydrate meal, with and without an insulin bolus provided at mealtime, with the desired range of 70–180 mg/dL also plotted; while it is clearly important to provide an insulin bolus at mealtime, it is known that many adolescents fail to do this two or more times a week, leading to higher mean BG levels.

Automated Insulin Dosing for Type 1 Diabetes, Fig. 2

Steady-state relationship between insulin delivery and BG, for three different insulin sensitivities. The nominal condition used in the dynamic simulations that follow is shown as the “x” (1.058 U/h, 120 mg/dl)

Automated Insulin Dosing for Type 1 Diabetes, Fig. 3

Nominal sensitivity and open-loop simulations for a 50 g carbohydrate meal. Desired range of 70–180 mg/dl is shown. Illustrates the importance of providing an insulin bolus at mealtime

The closed-loop (using PID) simulation study shown in Fig. 4 is for breakfast, lunch, dinner, and a snack of 75, 50, 75, and 40 g, respectively; a scenario with feedforward/feedback control (insulin bolus at mealtime) is compared with feedback only. Clearly much better results can be achieved when a “meal announcement” is given so that an insulin bolus can be delivered; the artificial pancreas literature refers to this feedforward/feedback strategy as “hybrid control.” Forlenza et al. (2018) have shown clinically the BG control improvement when an insulin bolus is given 20 min ahead of the meal vs. using only feedback control action.

Clinical Trial Results

Much effort is required to conduct clinical trials, including (in the United States) approvals from an Institute Review Board (IRB), an FDA Investigational Device Exemption (IDE), review by a data safety management (DSMB) team, and clinical trials registration; see Bequette et al. (2016, 2018) for overviews of the regulatory process. Initially, simulation-based studies are conducted to validate expected algorithm performance (Patek et al. 2009). Typically, system safety is then verified in a hospital or clinical research center. These are often followed, after DSMB

Automated Insulin Dosing for Type 1 Diabetes, Fig. 4

Closed-loop simulations of PID-based feedback with and without feedforward control. Nominal sensitivity with three meals (75, 50, 75 g) and a snack (40 g); desired range of 70–180 mg/dl is shown. Illustrates the importance of providing an insulin bolus at mealtime (feedforward or meal announcement)

A

review and perhaps another IDE, by supervised outpatient studies in a hotel or diabetes camp and then by short- and long-term outpatient studies at home. Clinical studies have been inconsistent with performance metrics, so Maahs et al. (2016) proposed clinical trial metrics that include mean CGM as well as %CGM time in range for a large number of ranges. A recent review of clinical trial results is presented by Boughton and Hovorka (2019), for both single (insulin) and multi-hormone (insulin + glucagon) studies.

Buckingham and co-workers, in a series of articles, studied 160 subjects over 5722 subject nights using a predictive low-glucose suspend (PLGS) algorithm and showed hypoglycemia reduction in all age groups. A modification to the algorithm also bolused insulin if the glucose was predicted to be high, using a predictive hypo-/hyper-glycemic mitigation (PHHM) algorithm; 58 subjects over 2436 subject nights were studied in this phase. The PLGS and PHHM studies are summarized in Bequette et al. (2018); PHHM can be viewed as a control-to-range algorithm focused on overnight care.

Pinsker et al. (2016) report clinical trial results of a head-to-head comparison of MPC and PID in a study involving 30 participants and concluded that MPC had better performance with more time in range and lower mean glucose. A Zone-MPC study by Forlenza et al. (2017) was designed for prolonged infusion set wear, specifically to increase the probability of infusion set failures,

in a 2-week study involving 19 subjects. While most studies use “meal announcement” (feed-forward control), Cameron et al. (2017) present results on a multiple model probabilistic predictive control (MMPPC) system that anticipates and detects meals and does not require meal announcement. An MMPPC-based study by Forlenza et al. (2018) demonstrates the improvement and control that can be achieved if meal insulin boluses are given 20 min in advance of the meal. Dassau et al. (2017) report a comprehensive study involving 29 subjects over 12 weeks. In the longest study to date, Musolino et al. (2019) propose a protocol for a 6-month study involving 130 participants; the nonlinear MPC algorithm developed by Hovorka et al. (2004) will be used in this study.

A number of studies use both insulin and glucagon. El-Khatib et al. (2010) report in-patient clinical studies using a PD controller that is active under certain glucose concentrations to manipulate glucagon. Insulin is administered based on an adaptive, model predictive control strategy with a very short prediction horizon, making it similar to a PID controller. Russell et al. (2014) present outpatient results for a 5-day study with 20 adults and 32 adolescents. Blauw et al. (2016) stress the advantages of using a single integrated device (rather than separate smartphones and pumps) to manipulate both insulin and glucagon in a 4-day study involving 10 subjects. El-Khatib et al. (2017) study 39 subjects in a dual-arm at-home

study of 11 days in closed-loop and 11 days in conventional therapy.

Commercial Devices

The first threshold-based low-glucose suspend system approved by the US FDA (in 2013) was the Medtronic 530G, while the Medtronic 640G uses a predictive low-glucose suspend algorithm. The first closed-loop system approved by the US FDA (in 2017) was the Medtronic 670G, which is commonly called a “hybrid closed-loop” system because meal announcement (an estimated of the amount of carbohydrates in the meal, with the associated insulin bolus) is required. Garg et al. (2017) report results on adolescents and adults in a 3-month at-home study using the 670G.

As of July 2019, a number of potential commercial devices have gone through various stages of clinical trials. Buckingham et al. (2018) report results for an OmniPod system based on the OmniPod patch pump, a Dexcom CGM, and a MPC algorithm developed by Doyle and co-workers at UCSB and Harvard. Brown et al. (2018) report a study involving five subjects and the use of a T:slim Pump, Dexcom CGM, and a “ControlIQ” algorithm developed at the University of Virginia by Kovatchev and co-workers. The iLet system by Damiano at Boston University is a device that delivers both insulin and glucagon; they plan to first commercialize the insulin-only system. Bigfoot Biomedical also has a closed-loop system under development, based on a model predictive control algorithm.

Do-It-Yourself (DIY) Movement

Frustrated by the slow development in commercial devices for automated insulin delivery, a large do-it-yourself community has started an open-source movement. Initial commercial CGM manufacturers did not provide a way of sharing CGM data in real time, leading to a community called Nightscout that shared ways of “hacking” CGMs to share data in real time in 2013 (Lee et al. 2017). Soon thereafter (2014)

the open APS movement began, allowing DIY “Loopers” to implement their own closed-loop systems (Lewis 2018). The general approach that was developed is similar to a model predictive control algorithm, using models to predict the effect of meals and insulin on future CGM values (Diamond et al. 2019). The algorithm calculates the current insulin bolus (when spread over a 30-min interval) that will yield the desired CGM value at the end of the prediction horizon (the insulin action time). This involves an algebraic calculation rather than an optimization problem that is used in traditional MPC; the calculated insulin is not delivered if any CGM is predicted to be below a hypoglycemic threshold during the prediction horizon. Barnard et al. (2018) discuss challenges and potential benefits of collaborations between DIY individuals, device manufacturers, regulatory agencies, and caregivers.

Summary and Future Directions

Automated insulin delivery systems are far more than control algorithms to regulate BG by manipulating insulin (and perhaps glucagon). It is important to have easy-to-calibrate (or calibration-free) sensors (CGM), insulin infusion pumps, and infusion sets that have a low failure rate and easy-to-use interfaces to make it clear whether the system is under manual (open) or automatic (closed) loop. System faults should result in defaulting to a safe mode, which again should be clear to the user.

Future systems will better integrate knowledge about lifestyle (predictable exercise, eating and sleep times) and will include the use of calendar information (e.g., lunch meeting) and additional sensors (such as accelerometers and gyroscope from a smart watch). Indeed, Navarathna et al. (2018) report preliminary results for detecting meal motions using a smart watch, enabling an advisory feedforward action for meal announcement.

It is desirable to reduce the number of devices that must be placed on the body for current AID systems, which include a CGM (with transmitter), insulin infusion catheter attached to an

insulin pump, and a smart phone or other device used for the controller. There is some activity toward incorporating the CGM and infusion set into the same device. Indeed, if these were incorporated into a patch pump that also contained the interface and algorithm, only a single device would need to be placed on the body. It is likely, however, that a smart phone would still be used to communicate with the patch pump which may be worn under clothing.

Technology, Stockholm, Sweden

Abstract

Truck transportation offers unique use cases for the early deployment of automation technologies. In this article, we first provide an overview of applications of automated vehicles in the truck industry, from simple cruise controllers to complex driverless functionalities. We then focus on two promising use cases of automated truck driving: platoon-based cooperative freight transportation and driverless transportation in mining sites. Platooning allows trucks to reduce energy consumption and greenhouse gas emissions of about 10%. The further removal of the driver in follower vehicles yields consistent economical benefits for the fleet owner. As platoon-capable trucks will always represent a small portion of the overall traffic, here, we discuss a control architecture for freight transportation that can support the efficient creation of platoons and coordinate trucks from different owners. The second use case is on driverless transportation in mining sites. A mining site is a controlled environment where the site operator has a good overview of what is happening and the amount of unforeseen events is limited. Transportation tasks tend to be repetitive, monotone, and suited for autonomous system. Here, we present a functional architecture that is able to support the driverless operation of trucks in such an environment.

ADAS · Truck platooning · Driverless truck · Vehicle control · Autonomous truck · Automation in mining sites · Cooperative

freight transportation · Adaptive cruise control · Vehicular chain

Introduction

In the recent years, we witnessed an increasing interest in the development of autonomous driving technologies for freight transportation. Initial efforts in driverless technologies focused on passenger cars thanks to their higher diffusion. Pioneering research carried out in the 1990s and early 2000s showed how automated vehicles can be a reality in the near future (Horowitz and Varaiya 2000; Broggi et al. 1999). Among research efforts, the demonstration within the PATH project of eight driverless vehicles driving at a tight platoon formation in 1997 (Shladover 2007) and the fully autonomous 60-mile drive in urban environment in the 2007 DARPA Grand Challenge (Buehler et al. 2007) are considered milestones in vehicle automation. These results encouraged original equipment manufacturers (OEMs), component suppliers, and technology start-ups to invest in driverless technology research. Thanks to highly viable business cases offered by the automation of freight transportation, a large research effort focused on the development of automated truck technologies.

Unlike the passenger car industry that is human-centered and more adverse to trends, the freight transportation is conservative and almost exclusively driven by operational efficiency. That means that any technology that can reduce the truck operational cost for even a few percent is able to attract significant attention and investments. Figure 1 shows some examples of relevant applications of truck automation currently under investigation by the industry. Figure 1a shows two long-haulage trucks of different brands driving in a platoon formation thanks to vehicle-to-vehicle communication and shared protocols for longitudinal dynamics automation. Due to the large cross-sectional area of trucks, the short inter-vehicular distance creates a slipstream effect that effectively reduces the overall energy consumption and

the greenhouse gas emissions of the platooning vehicles. Figure 1b presents an autonomous cabin-less vehicle hauling a container in a harbor freight terminal. A freight terminal is an example of a close environment where the site management system has an extensive awareness and control on what is happening. This drastically reduces the number of scenarios that automated vehicles have to face, compared to driving on public road. Furthermore, as these sites are typically closed, vehicle automation can be deployed without waiting for regulation for public road. Two other examples of autonomous trucks operating in controlled environments are

displayed in Fig. 1c, d. Figure 1c shows driverless haulers cooperating to transport ore and waste material across a mining site, while Fig. 1d shows the operation of two coordinated autonomous trucks removing snow from an airport runway.

Automating driving in truck operations encourages the optimization of the entire stack of logistic transportation. A glimpse of a possible freight transportation future is sketched in Fig. 2. Here, the fleet management system (FMS) portrayed by the watchtower governs and oversees the freight vehicles in the area. It has full knowledge of the requested flows of goods, their deadlines, and their dependencies. In order

(a) Multi-brand truck platoon driving on public road.

(b) Self-driving hauler operating in a freight terminal.

(c) Driverless haulers operating in an open-pit mining site.

(d) Autonomous snow removal trucks operating in an airport.

ating in a freight terminal (c) Driverless haulers operating in an open-pit mining site (d) Autonomous snow removal trucks operating in an airport

Automated Truck Driving, Fig. 2 Glimpse of a possible future of automated freight transportation. (Image courtesy of Scania)

to cope with the requests, it creates transport missions and assigns them to the automated trucks. As trucks can greatly vary in type of transported goods and maximum load, the correct dispatch of vehicles can substantially improve the transportation efficiency. The system can assign large flows of goods with the same origin and destination to multiple trucks driving in platoon formation or promote the creation of platoons between trucks driving along the same road to further improve efficiency. Not least, the FMS dispatch solution should be robust to possible delay and adapt when live updates are received.

SAE Levels of Automation Applied to Trucks

In 2015, SAE published the J3016 standard (SAE International 2018) that defines six levels of vehicle automation. The standard applies to all on-road vehicles, and its main intent was to clearly separate the responsibility of the driver versus the automated system. Although other vehicle autonomy classifications have been proposed, SAE J3016 has been widely adopted by industry and, nowadays, is considered the de facto standard for vehicle automation. The six levels of automation are summarized in Table 1, and their application in the truck industry is discussed below.

Level 0: No Automation

At level 0, the driver is fully in control of the vehicle. His/her driving experience can be enhanced by passive advanced driver assistance systems (ADAS) that monitor the environment and trigger audio and visual warnings, e.g., lane departure, forward collision, and blind spot detection. Such systems are nowadays common in commercial trucks.

Level 1: Driver Assistance

At level 1, the driver is assisted by an active ADAS that acts either on the steering or on the acceleration/deceleration. The driver, however, is expected to monitor the automated system at all times and overrule it if needed. The driver is ultimately responsible for the driving task.

Safety-related active ADAS, such as automatic emergency braking, adaptive cruise control, and lane keeping assist, has proven capable of significantly reducing the number of road crashes (IIHS-HLDI 2019). In the truck industry, active ADAS that relies on vehicle-to-vehicle (V2V) and vehicle-to-infrastructure (V2I) communications is also deployed to improve efficiency and safety.

Predictive cruise controllers based on V2I communication allow to exploit information on the road ahead, e.g., road topography, traffic condition, or traffic light timing, to adapt the

Automated Truck Driving, Table 1 SAE levels of automation

SAE level	Description
Level 0 No automation	The driver performs all driving tasks
Level 1 Driver assistance	The driver is assisted by an autonomous driving feature acting on either steering or acceleration/deceleration
Level 2 Partial automation	The driver is supported by one or more driving assistance features acting on both the steering and acceleration/deceleration. The driver is expected to monitor at all times the automated system
Level 3 Conditional automation	Under certain conditions, all driving tasks are automated. The driver can divert the attention temporally but should be ready to take control of the vehicle in a few seconds when the system requires it
Level 4 High automation	Under certain conditions, all driving tasks are automated. Under all conditions, the system is able to take the vehicle to a minimal risk condition
Level 5 Full automation	All driving tasks are automated under all conditions

A

current speed and reduce inefficient braking. Topography-aware predictive cruise controllers are commercially available (Daimler 2020; VolvoTrucks 2020), while cruise controllers that exploit traffic condition and traffic light timing are still subjects of research (Henriksson et al. 2017; Cicic and Johansson 2018).

V2V communication allows adjacent vehicles to share their current state and future intention, enabling safe and efficient operation of truck platooning through longitudinal dynamics automation. An example of a three-truck level 1 platoon is depicted in Fig. 3. Due to the large cross-sectional area of trucks, the short inter-vehicular distance creates a slipstream effect that translates into a reduction of energy consumption and greenhouse gas emissions of the order of 10% (Browand et al. 2004; Roeth 2013; Alam et al. 2015). In long-haulage transportation, this reduction has a notable impact on the overall operational cost and has therefore attracted major investments in OEMs and start-ups, e.g., Ensemble (2020) and Peloton (2020).

Level 2: Partial Automation

The driver is assisted by one or more ADAS that acts on both the steering and acceleration/deceleration in level 3 automation. As in

level 1 automation, however, the driver should monitor the automated systems at all times and be ready to overrule them if needed. The driver is ultimately responsible for the driving task.

Level 2 automation allows the concurrent use of multiple ADAS. In truck platooning, it allows the simultaneous automated control of the longitudinal and lateral dynamics, enabling tighter inter-vehicular spacing (Engström et al. 2019).

Level 3: Conditional Automation

With level 3 automation, the vehicle is fully controlled by the automated system under certain conditions. Such conditions define the so-called operational design domain (ODD) and may include geographic limitations, environmental conditions (e.g., weather and daytime/nighttime), and vehicle status (e.g., driving alone or in platoon formation). Although the driver can diverge his/her attention to other tasks, he/she needs to be ready to take back the control of the vehicles in a few seconds when the system requires it and is ultimately responsible for the driving task.

In the truck industry, level 3 automation would allow the driver to conduct other tasks valuable for the business while sitting in the driver seat. However, level 3 automation is highly contro-

Automated Truck Driving, Fig. 3 Three long-haulage trucks using level 1 truck platooning functionality. (Image courtesy of Scania)

versial because, although the driver can engage in other tasks, he/she is still fully responsible if an emergency situation occurs. For this reasons, many truck manufacturers, despite having the technology, prefer to skip the commercialization of level 3 automation and focus instead on level 4 (TTNews 2020).

Level 4: High Automation

At level 4, the vehicle is fully automated under certain conditions defined by the ODD. If the ODD conditions are no more satisfied, the automated system is able to take the vehicle to a minimal risk state without human intervention. When the vehicle is operating in the autonomous mode, the automated system is fully responsible for the driving task. A human driver is therefore no more required in the vehicle, and if present, he/she can be fully engaged in other tasks. The latter clause is a game changer in vehicle automation and enables promising and highly valuable business cases. Furthermore, it also allows to remove humans from remote and dangerous sites (e.g., underground mining sites) and to respond to the increasing shortage of truck drivers in some parts of the world.

Level 4 automation is relatively broad, and its degree of complexity is highly dependent on the specified ODD. ODD can, for example, restrict the automation to certain locations or roads. Geofencing allows the use of highly detailed maps that may include visual waypoints,

road signs, and road works. These maps can facilitate environmental perception and path planning and, overall, simplify the automated system implementation. Promising use cases of geo-restricted level 4 automation are trucks operating in controlled environments, such as freight terminals, mine sites, and airports, as illustrated in Fig. 1. Another appealing use case is the restriction of level 4 automation to highways, which represent an environment with clear rules and a relatively low number of possible scenarios. Highway automation represents a strong business case that motivated the creation of new start-ups, e.g., Embark (2020). Level 4 platooning can represent one of the first implementations of driverless vehicles on public roads; see test scenarios in Singapore (2020).

Level 5: Full Automation

At level 5, all driving tasks are automated under all circumstances. The automated system is able to fully replace the human driver and, when activated, is fully responsible for the driving task.

Level 5 automation represents a major step from level 4 as the automated system should be able to handle any unforeseen event. Furthermore, as geofencing is not part of level 5 automation, it is probably impossible to make use of highly detailed environment maps. Because of its complexity and limited gain, level 5 automation is generally considered of limited interest currently in the truck industry.

Platoon-Based Cooperative Freight Transportation

In this section, we discuss in some detail the use case of cooperative freight transportation centered on platoons, and we discuss a multilayer control architecture to back it up.

Figure 3 shows three long-haulage trucks driving on a highway in platoon formation. As we have seen, platooning is capable of reducing truck energy consumption and greenhouse gas emissions of the order of 10%. More advanced platooning functionalities (level 4 platooning) would additionally allow to allocate the driver time on other tasks or to operate follower trucks driverless, resulting in significant economical benefits for transportation companies. Platoon-capable trucks, however, will always constitute only a fraction of the overall traffic, and their locations will therefore be relatively sparsely distributed over the road network. To back up the efficient exploitation of truck platooning in freight transportation, truck cooperation will play an essential role.

Figure 4 gives a synopsis of how a possible future of cooperative freight transportation based on platooning can look like. The figure shows not only multiple platoons but also trucks driving alone. Trucks generally have different origins; destinations; deadlines; platooning functionalities; and, if a human driver is present, rest constraints. To meet and form platoons, trucks need therefore to adjust their speed or stop at roadside stations. However, these actions cannot be conducted naively as short-sighted decisions can result in higher operation costs for the transportation companies. To cope with the matter, a central office displayed in the bottom right corner of the figure has a complete overview of truck missions and promotes the formation of platoons that are most beneficial for the overall freight transportation.

To support cooperative freight transportation, the multilayer control architecture in Fig. 5 is natural (Van De Hoef et al. 2019). Such architecture is composed of four layers that aim to provide increasingly higher levels of abstraction.

The lowest layer, the so-called operational layer, is where the vehicle controllers reside. Vehicle controllers are distributed in the platooning vehicles and, thanks to V2V communication and local sensors, guarantee the safe and efficient operation of platoons. Their goal is to track the reference speed and inter-vehicular distances by commanding the engine actuators, the brake systems, and the gearbox of platooning vehicles. One step above, in the tactical layer, resides the platoon manager. The platoon manager controls the formation, splitting, reorganization, and operation of platoons. It does so by defining the reference speed and inter-vehicular distances tracked by the vehicle controllers. The platoon manager typically runs in one of the trucks or in an off-board location. It can exploit information about the road ahead, e.g., road topography and traffic condition, to adjust the platoon reference speed and inter-vehicular distances to improve the efficiency (Turri et al. 2017; Cicic and Johansson 2018). One layer up, we find the strategic layer where the platoon coordinator resides. The platoon coordinator has a central role in the truck coordination task and defines which trucks should adjust their speed or momentarily stop in order to platoon together. This is a complex task, and both centralized and decentralized solutions have been proposed, e.g., van de Hoef et al. (2015) and Johansson et al. (2020). Finally, in the service layer, the transport management system (TMS) and the fleet management system (FMS) reside. This layer is responsible for assigning goods flows to vehicles and drivers, ranging from manual planning to complex supply chain optimization. A similar architecture is the base of the Ensemble project that aims at achieving platooning protocols between the major European truck manufacturers (Ensemble 2020).

Driverless Transportation in Mining Sites

Controlled environments are locations where we could expect early deployment of fully driverless vehicles. In this section, we discuss the use case

Automated Truck Driving, Fig. 4 Future scenario of cooperative freight transportation centered on truck platooning

Automated Truck Driving, Fig. 8 Functional architecture for autonomous driving (Lima 2018)

of driverless transportation in one such environment, namely, a mining site. Mining sites require a considerable transfer of materials, such as ore and waste, on distances that can stretch up to

hundreds of kilometers. Nowadays, the transportation operations in mining sites are carried out by human drivers. Their job is considered repetitive and dangerous, and due to their

often remote location, the sector experiences a widespread shortage of drivers. Removing human drivers in mines is therefore a quite attractive quest that can result in significant economical and safety benefits.

Figure 6 shows a test vehicle for driverless transportation in mining sites. The vehicle is equipped with short-range radars at each corner for 360-degree obstacle detection, long-range radar to enable high-speed driving, multi-lens cameras to identify objects, and inertial measurement unit (IMU) for acceleration measurements. A possible scenario where such vehicle can operate is illustrated in Fig. 7. Here, we see a truck autonomously driving from a pickup location to an off-load location. This truck does not need a driver onboard as its operation can be monitored by a remote operator working at an off-site office.

Figure 8 shows a functional architecture for a self-driving vehicle system (Lima 2018). The architecture integrates a variety of sensors, which through sensor fusion provides situational awareness to the driverless vehicle, enabling the safe planning and control of the vehicle motion. The route planning specifies the mission for the driverless vehicle, e.g., going from the pickup to the drop-off location. While travelling between these two points, the vehicle needs to detect objects and unexpected obstacles. This task is fulfilled by the perception functionality and is enabled, in its turn, by a multitude of vehicle sensors. A typical set of sensors for autonomous vehicles include (i) radars that measure distances to obstacles in specific directions, (ii) one or more lidars that provide a 3D map of the environment, (iii) an inertial measurement unit (IMU) that measures linear and angular accelerations, and (iv) monocular and stereo cameras that recognize objects and estimate their distance. The perception functionality fuses all the sensor information and returns a labelled map of the environment. Here, labels specify the particular object or obstacle in the map, e.g., site walls, road signs, humans, and other vehicles. The labelled map is then processed by the situational awareness functionality that, by exploiting GPS measures and detailed off-

board maps, understands the scene and selects the proper behavior to follow, e.g., proceed normally, stand still, or circumnavigate obstacle. The selected behavior is communicated to the motion planner that computes the reference vehicle trajectory accordingly. Finally, the *motion controller* governs the actuators, i.e., powertrain, brakes, and steering, while tracking the reference trajectory. The primary control system is often backed up by a secondary system able to operate the vehicle even in the case of partially faulty hardware. If supported, it can take the vehicle to a state of minimal risk, e.g., to a standstill position on the side of the road.

Autotuning

Tore Hägglund

Lund University, Lund, Sweden

A

Abstract

Autotuning, or automatic tuning, means that the controller is tuned automatically. Autotuning is normally applied to PID controllers, but the technique can also be used to initialize more advanced controllers. The main approaches to autotuning are based on step response analysis or frequency response analysis obtained using relay feedback. Autotuning has been well received in industry, and today most distributed control systems have some kind of autotuning technique.

Keywords

Automatic tuning · Gain scheduling · PID control · Process control · Proportional-integral-derivative control · Relay feedback

Background

In the late 1970s and early 1980s, there was a quite rapid change of controller implementation in process control. The analog controllers were replaced by computer-based controllers and distributed control systems. The functionality of the new controllers was often more or less a copy of the old analog equipment, but new functions that utilized the computer implementation were gradually introduced. One of the first functions of this type was autotuning. Autotuning is a method to tune the controllers, normally PID controllers, automatically.

What Is Autotuning?

A PID controller in its basic form has the structure

$$u(t) = K \left(e(t) + \frac{1}{T_i} \int_0^t e(\tau) d\tau + T_d \frac{d}{dt} e(t) \right),$$

where u is the controller output and $e = y_{sp} - y$ is the control error, where y_{sp} is the setpoint and y is the process output. There are three parameters in the controller, gain K , integral time T_i , and derivative time T_d . These parameters have to be set by the user. Their values are dependent of the process dynamics and the specifications of the control loop.

A process control plant may have thousands of control loops, which means that maintaining high-performance controller tuning can be very time consuming. This was the main reason why procedures for automatic tuning were installed so rapidly in the computer-based controllers.

When a controller is to be tuned, the following steps are normally performed by the user:

1. To determine the process dynamics, a minor disturbance is injected by changing the control signal.
2. By studying the response in the process output, the process dynamics can be determined, i.e., a process model is derived.
3. The controller parameters are finally determined based on the process model and the specifications.

Autotuning means simply that these three steps are performed automatically. Instead of having a human to perform these tasks, they are performed automatically on demand from the user. Ideally, the autotuning should be fully automatic, which means that no information about the process dynamics is required from the user.

Automatic tuning can be performed in many ways. The process disturbance can take different forms, e.g., in the form of step changes or some kind of oscillatory excitation. The model obtained can be more or less accurate. There are also many ways to tune the controller based on the process model.

Here, we will discuss two main approaches for autotuning, namely, those that are based on step response analysis and those that are based on frequency response analysis.

Methods Based on Step Response Analysis

Most methods for automatic tuning of PID controllers are based on step response analysis. When the operator wishes to tune the controller, an open-loop step response experiment is performed. A process model is then obtained from the step response, and controller parameters are determined. This is usually done using simple formulas or look-up tables.

The most common process model used for PID controller tuning based on step response experiments is the first-order plus dead-time model

$$G(s) = \frac{K_p}{1 + sT} e^{-sL}$$

where K_p is the static gain, T is the apparent time constant, and L is the apparent dead time. These three parameters can be obtained from a step response experiment according to Fig. 1.

Static gain K_p is given by the ratio between the steady-state change in process output and the magnitude of the control signal step,

Autotuning, Fig. 1 Determination of K_p , L , and T from a step response experiment

$K_p = \Delta y / \Delta u$. Dead-time L is determined from the time elapsed from the step change to the intersection of the largest slope of the process output with the level of the process output before the step change. Finally, time constant T is the time when the process output has reached 63 % of its final value, subtracted by L .

The greatest difficulty in carrying out tuning automatically is in selecting the amplitude of the step. The user naturally wants the disturbance to be as small as possible so that the process is not disturbed more than necessary. On the other hand, it is easier to determine the process model if the disturbance is large. The result of this dilemma is usually that the user has to decide how large the step in the control signal should be. Another problem is to determine when the step response has reached its final value.

Methods Based on Frequency Response Analysis

Frequency-domain characteristics of the process can be obtained by adding sinusoids to the control signal, but without knowing the frequency response of the process, the interesting frequency range and acceptable amplitudes are not known. A method that automatically provides a relevant frequency response can be determined from experiments with relay feedback according to Fig. 2. Notice that there is a switch that selects either relay feedback or ordinary PID feedback. When it is desired to tune the system, the PID function is disconnected and the system is connected to relay feedback control. Relay feedback control is the same as on/off control, but where the on and off levels are carefully chosen and not

0 and 100 %. The relay feedback makes the control loop oscillate. The period and the amplitude of the oscillation is determined when steady-state oscillation is obtained. This gives the ultimate period and the ultimate gain. The parameters of a PID controller can then be determined from these values. The PID controller is then automatically switched in again, and the control is executed with the new PID parameters.

For large classes of processes, relay feedback gives an oscillation with period close to the ultimate frequency ω_u , as shown in Fig. 3, where the control signal is a square wave and the process output is close to a sinusoid. The gain of the transfer function at this frequency is also easy to obtain from amplitude measurements.

Describing function analysis can be used to determine the process characteristics. The describing function of a relay with hysteresis is

$$N(a) = \frac{4d}{\pi a} \left(\sqrt{1 - \left(\frac{\epsilon}{a}\right)^2} - i \frac{\epsilon}{a} \right)$$

where d is the relay amplitude, ϵ the relay hysteresis, and a the amplitude of the input signal. The negative inverse of this describing function is a straight line parallel to the real axis; see Fig. 4. The oscillation corresponds to the point where the negative inverse describing function crosses the Nyquist curve of the process, i.e., where

$$G(i\omega) = -\frac{1}{N(a)}$$

Since $N(a)$ is known, $G(i\omega)$ can be determined from the amplitude a and the frequency ω of the oscillation.

Notice that the relay experiment is easily automated. There is often an initialization phase where the noise level in the process output is determined during a short period of time. The noise level is used to determine the relay hysteresis and a desired oscillation amplitude in the process output. After this initialization phase, the relay function is introduced. Since the amplitude of the oscillation is proportional to the relay output, it is easy to control it by adjusting the relay output.

Autotuning, Fig. 2 The relay autotuner. In the tuning mode the process is connected to relay feedback

Autotuning, Fig. 3 Process output y and control signal u during relay feedback

Autotuning, Fig. 4 The negative inverse describing function of a relay with hysteresis $-1/N(a)$ and a Nyquist curve $G(i\omega)$

Different Adaptive Techniques

In the late 1970s, at the same time as autotuning procedures were developed and implemented in industrial controllers, there was a large academic interest in adaptive control. These two concepts are often mixed up with each other. Autotuning is sometimes called tuning on demand. An identification experiment is performed, controller

parameters are determined, and the controller is then run with fixed parameters. An adaptive controller is, however, a controller where the controller parameters are adjusted online based on information from routine data. Automatic tuning and adaptive control have, however, one thing in common, namely, that they are methods to adapt the controller parameters to the actual process dynamics. Therefore, they are both called *adaptive techniques*.

There is a third adaptive technique, namely, gain scheduling. Gain scheduling is a system where controller parameters are changed depending on measured operating conditions. The scheduling variable can, for instance, be the measurement signal, controller output, or an external signal. For historical reasons the word gain scheduling is used even if other parameters like integral time or derivative time are changed. Gain scheduling is a very effective way of controlling systems whose dynamics change with the operating conditions. Automatic tuning has made it possible to generate gain schedules automatically.

Although research on adaptive techniques has almost exclusively focused on adaptation,

Autotuning, Fig. 5 When to use different adaptive techniques

experience has shown that autotuning and gain scheduling have much wider industrial applicability. Figure 2 illustrates the appropriate use of the different techniques.

Controller performance is the first issue to consider. If requirements are modest, a controller with constant parameters and conservative tuning can be used. Other solutions should be considered when higher performance is required.

If the process dynamics are constant, a controller with constant parameters should be used. The parameters of the controller can be obtained by autotuning.

If the process dynamics or the character of the disturbances are changing, it is useful to compensate for these changes by changing the controller. If the variations can be predicted from measured signals, gain scheduling should be used since it is simpler and gives superior and more robust performance than continuous adaptation. Typical examples are variations caused by nonlinearities in the control loop. Autotuning can be used to build up the gain schedules automatically.

There are also cases where the variations in process dynamics are not predictable. Typical examples are changes due to unmeasurable variations in raw material, wear, fouling, etc. These variations cannot be handled by gain scheduling but must be dealt with by adaptation. An autotuning procedure is often used to initialize the

adaptive controller. It is then sometimes called pre-tuning or initial tuning.

To summarize, autotuning is a key component in all adaptive techniques and a prerequisite for their use in practice.

Industrial Products

Commercial PID controllers with adaptive techniques have been available since the beginning of the late 1970s, both in single-station controllers and in distributed control systems.

Two important, but distinct, applications of PID autotuners are *temperature controllers* and *process controllers*. Temperature controllers are primarily designed for temperature control, whereas process controllers are supposed to work for a wide range of control loops in the process industry such as flow, pressure, level, temperature, and concentration control loops. Automatic tuning is easier to implement in temperature controllers, since most temperature control loops have several common features. This is the main reason why automatic tuning was introduced more rapidly in these controllers.

Since the processes that are controlled with process controllers may have large differences in their dynamics, tuning becomes more difficult compared to the pure temperature control loops.

Automatic tuning can also be performed by external devices which are connected to the

control loop during the tuning phase. Since these devices are supposed to work together with controllers from different manufacturers, they must be provided with quite a lot of information about the controller structure and parameterization in order to provide appropriate controller parameters. Such information includes signal ranges, controller structure (series or parallel form), sampling rate, filter time constants, and units of the different controller parameters (gain or proportional band, minutes or seconds, time or repeats/time).

Summary and Future Directions

Most of the autotuning methods that are available in industrial products today were developed about 30 years ago, when computer-based controllers started to appear. These autotuners are often based on simple models and simple tuning rules. With the computer power available today, and the increased knowledge about PID controller design, there is a potential for improving the autotuners, and more efficient autotuners will probably appear in industrial products quite soon.

Averaging Algorithms and Consensus

Wei Ren

Department of Electrical Engineering,
University of California, Riverside, CA, USA

Abstract

In this article, we overview averaging algorithms and consensus in the context of distributed coordination and control of networked systems. The two subjects are closely related but not identical. Distributed consensus means that a team of agents reaches an agreement on certain variables of interest by interacting with their neighbors. Distributed averaging aims at computing the average of certain variables of interest among multiple agents by local communication. Hence averaging can be treated as a special case of consensus – average consensus. For distributed consensus, we introduce distributed algorithms for agents with single-integrator, general linear, and nonlinear dynamics. For distributed averaging, we introduce static and dynamic averaging algorithms. The former is useful for computing the average of initial conditions (or constant signals), while the latter is useful for computing the average of time-varying signals. Future research directions are also discussed.

Keywords

Cooperative control · Coordination ·
Distributed control · Multi-agent systems ·
Networked systems

Introduction

In the area of control of networked systems, low cost, high adaptivity and scalability, great robustness, and easy maintenance are critical factors. To achieve these factors, distributed coordination and control algorithms that rely on only local interaction between neighboring agents to

achieve collective group behavior are more favorable than centralized ones. In this article, we overview averaging algorithms and consensus in the context of distributed coordination and control of networked systems.

Distributed consensus means that a team of agents reaches an agreement on certain variables of interest by interacting with their neighbors. A consensus algorithm is an update law that drives the variables of interest of all agents in the network to converge to a common value (Jadbabaie et al. 2003; Olfati-Saber et al. 2007; Ren and Beard 2008). Examples of the variables of interest include a local representation of the center and shape of a formation, the rendezvous time, the length of a perimeter being monitored, the direction of motion for a multi-vehicle swarm, and the probability that a target has been identified. Consensus algorithms have applications in rendezvous, formation control, flocking, attitude alignment, and sensor networks (Bullo et al. 2009; Qu 2009; Mesbahi and Egerstedt 2010; Ren and Cao 2011; Bai et al. 2011a). Distributed averaging algorithms aim at computing the average of certain variables of interest among multiple agents by local communication. Distributed averaging finds applications in distributed computing, distributed signal processing, and distributed optimization (Tsitsiklis et al. 1986). Hence the variables of interest are dependent on the applications (e.g., a sensor measurement or a network quantity). Consensus and averaging algorithms are closely connected and yet nonidentical. When all agents are able to compute the average, they essentially reach a consensus, the so-called average consensus. On the other hand, when the agents reach a consensus, the consensus value might or might not be the average value.

Graph Theory Notations. Suppose that there are n agents in a network. A *network topology* (equivalently, *graph*) G consisting of a node set $\mathcal{V} = \{1, \dots, n\}$ and an edge set $\mathcal{E} \subseteq \mathcal{V} \times \mathcal{V}$ will be used to model *interaction* (communication or sensing) between the n agents. An *edge* (i, j) in a *directed graph* denotes that agent j can obtain

information from agent i , but not necessarily vice versa. In contrast, an edge (i, j) in an *undirected graph* denotes that agents i and j can obtain information from each other. Agent j is a (*in-*)*neighbor* of agent i if $(j, i) \in \mathcal{E}$. Let $\mathcal{N}_i$ denote the neighbor set of agent i . We assume that $i \in \mathcal{N}_i$. A *directed path* is a sequence of edges in a directed graph of the form $(i_1, i_2), (i_2, i_3), \dots$, where $i_j \in \mathcal{V}$. An *undirected path* in an undirected graph is defined analogously. A directed graph is *strongly connected* if there is a directed path from every agent to every other agent. An undirected graph is *connected* if there is an undirected path between every pair of distinct agents. A directed graph *has a directed spanning tree* if there exists at least one agent that has directed paths to all other agents. For example, Fig. 1 shows a directed graph that has a directed spanning tree but is not strongly connected. The *adjacency matrix* $\mathcal{A} = [a_{ij}] \in \mathbb{R}^{n \times n}$ associated with G is defined such that a_{ij} (the weight of edge (j, i)) is positive if agent j is a neighbor of agent i while $a_{ij} = 0$ otherwise. The (nonsymmetric) *Laplacian matrix* (Agaev and Chebotarev 2005) $\mathcal{L} = [\ell_{ij}] \in \mathbb{R}^{n \times n}$ associated with $\mathcal{A}$ and hence G is defined as $\ell_{ii} = \sum_{j \neq i} a_{ij}$ and $\ell_{ij} = -a_{ij}$ for all $i \neq j$. For an undirected graph, we assume that $a_{ij} = a_{ji}$. A graph is *balanced* if for every agent the total edge weights of its incoming links is equal to the total edge weights of its outgoing links ($\sum_{j=1}^n a_{ij} = \sum_{j=1}^n a_{ji}$ for all i).

Averaging Algorithms and Consensus, Fig. 1 A directed graph that characterizes the interaction among five agents, where A_i , $i = 1, \dots, 5$, denotes agent i . An *arrow* from agent j to agent i indicates that agent i receives information from agent j . The directed graph has a directed spanning tree but is not strongly connected. Here both agents 1 and 2 have directed paths to all other agents

Consensus

Consensus has a long history in management science, statistical physics, and distributed computing and finds recent interests in distributed control. While in the area of distributed control of networked systems the term *consensus* was initially more or less dominantly referred to the case of a continuous-time version of a distributed linear averaging algorithm, such a term has been broadened to a great extent later on. Related problems to consensus include synchronization, agreement, and rendezvous. The study of consensus can be categorized in various manners. For example, in terms of the final consensus value, the agents could reach a consensus on the average, a weighted average, the maximum value, the minimum value, or a general function of their initial conditions, or even a (changing) state that serves as a reference. A consensus algorithm could be linear or nonlinear. Consensus algorithms can be designed for agents with linear or nonlinear dynamics. As the agent dynamics become more complicated, so do the algorithm design and analysis. Numerous issues are also involved in consensus such as network topologies (fixed vs. switching, deterministic vs. random, directed vs. undirected, asynchronous vs. synchronous), time delay, quantization, optimality, sampling effects, and convergence speed. For example, in real applications, due to nonuniform communication/sensing ranges or limited field of view of sensors, the network topology could be directed rather than undirected. Also due to unreliable communication/sensing and limited communication/sensing ranges, the network topology could be switching rather than fixed.

Consensus for Agents with Single-Integrator Dynamics

We start with a fundamental consensus algorithm for agents with single-integrator dynamics. The results in this section follow from Jadbabaie et al. (2003), Olfati-Saber et al. (2007), Ren and Beard (2008), Moreau (2005), and Agaev and Chebotarev (2000). Consider agents with single-integrator dynamics

$$\dot{x}_i(t) = u_i(t), \quad i = 1, \dots, n, \quad (1)$$

where x_i is the state and u_i is the control input. A common consensus algorithm for (1) is

$$u_i(t) = \sum_{j \in \mathcal{N}_i(t)} a_{ij}(t)[x_j(t) - x_i(t)], \quad (2)$$

where $\mathcal{N}_i(t)$ is the neighbor set of agent i at time t and $a_{ij}(t)$ is the (i, j) entry of the adjacency matrix $\mathcal{A}$ of the graph $\mathcal{G}$ at time t . A consequence of (2) is that the state $x_i(t)$ of agent i is driven toward the states of its neighbors or equivalently toward the weighted average of its neighbors' states. The closed-loop system of (1) using (2) can be written in matrix form as

$$\dot{x}(t) = -\mathcal{L}(t)x(t), \quad (3)$$

where x is a column stack vector of all x_i and $\mathcal{L}$ is the Laplacian matrix. Consensus is *reached* if for all initial states, the agents' states eventually become identical. That is, for all $x_i(0)$, $\|x_i(t) - x_j(t)\|$ approaches zero eventually.

The properties of the Laplacian matrix $\mathcal{L}$ play an important role in the analysis of the closed-loop system (3). When the graph $\mathcal{G}$ (and hence the associated Laplacian matrix $\mathcal{L}$) is fixed, (3) can be analyzed by studying the eigenvalues and eigenvectors of $\mathcal{L}$. Due to its special structure, for any graph $\mathcal{G}$, the associated Laplacian matrix $\mathcal{L}$ has at least one zero eigenvalue with an associated right eigenvector $\mathbf{1}$ (column vector of all ones) and all other eigenvalues have positive real parts. To ensure consensus, it is equivalent to ensure that $\mathcal{L}$ has a simple zero eigenvalue. It can be shown that the following three statements are equivalent: (i) the agents reach a consensus exponentially for arbitrary initial states; (ii) the graph $\mathcal{G}$ has a directed spanning tree; and (iii) the Laplacian matrix $\mathcal{L}$ has a simple zero eigenvalue with an associated right eigenvector $\mathbf{1}$ and all other eigenvalues have positive real parts. When consensus is reached, the final consensus value is a weighted average of the initial states of those agents that have directed paths to all other agents (see Fig. 3 for an illustration).

When the graph $G(t)$ is switching at time instants $t_0, t_1, \dots$, the solution to the closed-loop system (3) is given by $x(t) = \Phi(t, 0)x(0)$, where $\Phi(t, 0)$ is the transition matrix corresponding to $-\mathcal{L}(t)$. Consensus is reached if $\Phi(t, 0)$ eventually converges to a matrix with identical rows. Here $\Phi(t, 0) = \Phi(t, t_k)\Phi(t_k, t_{k-1}) \cdots \Phi(t_1, 0)$, where $\Phi(t_k, t_{k-1})$ is the transition matrix corresponding to $\mathcal{L}(t)$ at time interval $[t_{k-1}, t_k]$. It turns out that each transition matrix is a *row-stochastic* matrix with positive diagonal entries. A square matrix is row stochastic if all its entries are nonnegative and all of its row sums are one. The consensus convergence can be analyzed by studying the product of row-stochastic matrices. Another analysis technique is a Lyapunov approach (e.g., $\max x_i - \min x_i$). It can be shown that the agents' states reach a consensus if there exists an infinite sequence of contiguous, uniformly bounded time intervals, with the property that across each such interval, the union of the graphs $G(t)$ has a directed spanning tree. That is, across each such interval, there exists at least one agent that can directly or indirectly influence all other agents. It is also possible to achieve certain nice features by designing nonlinear consensus algorithms of the form $u_i(t) = \sum_{j \in \mathcal{N}_i(t)} a_{ij}(t) \psi[x_j(t) - x_i(t)]$, where $\psi(\cdot)$ is a nonlinear function satisfying certain properties. One example is a continuous nondecreasing odd function. For example, a saturation type function could be introduced to account for actuator saturation and a signum type function could be introduced to achieve finite-time convergence.

As shown above, for single-integrator dynamics, the consensus convergence is determined entirely by the network topologies. The primary reason is that the single-integrator dynamics are internally stable. However, when more complicated agent dynamics are involved, the consensus algorithm design and analysis become more complicated. On one hand, whether the graph is undirected (respectively, switching) or not has significant influence on the complexity of the consensus analysis. On the other hand, not only the network topology but also the agent dynamics themselves and the parameters in the consensus algorithm play important roles. Next we

introduce consensus for agents with general linear and nonlinear dynamics.

Consensus for Agents with General Linear Dynamics

In some circumstances, it is relevant to deal with agents with general linear dynamics, which can also be regarded as linearized models of certain nonlinear dynamics. The results in this section follow from Li et al. (2010). Consider agents with general linear dynamics

$$\dot{x}_i = Ax_i + Bu_i, \quad y_i = Cx_i, \quad (4)$$

where $x_i \in \mathbb{R}^m$, $u_i \in \mathbb{R}^p$, and $y_i \in \mathbb{R}^q$ are, respectively, the state, the control input, and the output of agent i and A, B, C are constant matrices with compatible dimensions.

When each agent has access to the relative states between itself and its neighbors, a distributed static consensus algorithm is designed for (4) as

$$u_i = cK \sum_{j \in \mathcal{N}_i} a_{ij}(x_i - x_j), \quad (5)$$

where $c > 0$ is a coupling gain, $K \in \mathbb{R}^{p \times m}$ is the feedback gain matrix, and $\mathcal{N}_i$ and a_{ij} are defined as in (2). It can be shown that if the graph G has a directed spanning tree, consensus is reached using (5) for (4) if and only if all the matrices $A + c\lambda_i(\mathcal{L})BK$, where $\lambda_i(\mathcal{L}) \neq 0$ are Hurwitz. Here $\lambda_i(\mathcal{L})$ denotes the i th eigenvalue of the Laplacian matrix $\mathcal{L}$. A necessary condition for reaching a consensus is that the pair (A, B) is stabilizable. The consensus algorithm (5) can be designed via two steps:

- Solve the linear matrix inequality $A^T P + PA - 2BB^T < 0$ to get a positive-definite solution P . Then let the feedback gain matrix $K = -B^T P^{-1}$.
- Select the coupling strength c larger than the threshold value $1 / \min_{\lambda_i(\mathcal{L}) \neq 0} \text{Re}[\lambda_i(\mathcal{L})]$, where $\text{Re}(\cdot)$ denotes the real part.

Note that here the threshold value depends on the eigenvalues of the Laplacian matrix, which

Averaging Algorithms and Consensus, Fig. 2

Consensus for five agents using the algorithm (2) for (1). Here the graph $\mathcal{G}$ is given by Fig. 1. The initial states are chosen as $x_i(0) = 2i$, where $i = 1, \dots, 5$. Consensus is reached as $\mathcal{G}$ has a directed spanning tree. The final consensus value is a weighted average of the initial states of agents 1 and 2

is in some sense global information. To overcome such a limitation, it is possible to introduce adaptive gains in the algorithm design. The gains could be updated dynamically using local information.

When the relative states between each agent and its neighbors are not available, one is motivated to make use of the output information and employ observer-based design to estimate the relative states. An observer-type consensus algorithm is designed for (4) as

$$\begin{aligned} \dot{v}_i &= (A + BF)v_i + cL \sum_{j \in \mathcal{N}_i} a_{ij} [C(v_i - v_j) \\ &\quad - (y_i - y_j)], \\ u_i &= Fv_i, \quad i = 1, \dots, n, \end{aligned} \quad (6)$$

where $v_i \in \mathbb{R}^m$ are the observer states, $F \in \mathbb{R}^{p \times n}$ and $L \in \mathbb{R}^{m \times q}$ are the feedback gain matrices, and $c > 0$ is a coupling gain. Here the algorithm (6) uses not only the relative outputs between each agent and its neighbors but also its own and neighbors' observer states. While relative outputs could be obtained through local measurements, the neighbors' observer states can only be obtained via communication. It can be shown that if the graph $\mathcal{G}$ has a directed spanning tree, consensus is reached using (6) for (4) if the matrices $A + BF$ and $A + c\lambda_i(L)LC$, where $\lambda_i(L) \neq 0$, are Hurwitz. The

observer-type consensus algorithm (6) can be seen as an extension of the single-system observer design to multi-agent systems. Here the *separation principle* of the traditional observer design still holds in the multi-agent setting in the sense that the feedback gain matrices F and L can be designed separately.

Consensus for Agents with Nonlinear Dynamics

In multi-agent applications, agents usually represent physical vehicles with special dynamics, especially nonlinear dynamics for the most part. Examples include Lagrangian systems for robotic manipulators and autonomous robots, nonholonomic systems for unicycles, attitude dynamics for rigid bodies, and general nonlinear systems. Similar to the consensus algorithms for linear multi-agent systems, the consensus algorithms used for these nonlinear agents are often designed based on state differences between each agent and its neighbors. But due to the inherent nonlinearity, the problem is more complicated and additional terms might be required in the algorithm design. The main techniques used in the consensus analysis for nonlinear multi-agent systems are often Lyapunov-based techniques (Lyapunov functions, passivity theory, nonlinear contraction analysis, and potential functions).

Early results on consensus for agents with nonlinear dynamics primarily focus on

undirected graphs to exploit the symmetry to facilitate the construction of Lyapunov function candidates. Unfortunately, the extension from an undirected graph to a directed one is nontrivial. For example, the directed graph does not preserve the passivity properties in general. Moreover, the directed graph could cause difficulties in the design of (positive-definite) Lyapunov functions. One approach is to integrate the nonnegative left eigenvector of the Laplacian matrix associated with the zero eigenvalue into the Lyapunov function, which is valid for strongly connected graphs and has been applied in some problems. Another approach is based on sliding mode control. The idea is to design a sliding surface for reaching a consensus. Taking multiple Lagrangian systems as an example, the agent dynamics are represented by

$$\begin{aligned} M_i(q_i)\ddot{q}_i + C_i(q_i, \dot{q}_i)\dot{q}_i + g_i(q_i) &= \tau_i, \\ i &= 1, \dots, n, \end{aligned} \quad (7)$$

where $q_i \in \mathbb{R}^p$ is the vector of generalized coordinates, $M_i(q_i) \in \mathbb{R}^{p \times p}$ is the symmetric positive-definite inertia matrix, $C_i(q_i, \dot{q}_i)\dot{q}_i \in \mathbb{R}^p$ is the vector of Coriolis and centrifugal torques, $g_i(q_i) \in \mathbb{R}^p$ is the vector of gravitational torque, and $\tau_i \in \mathbb{R}^p$ is the vector of control torque on the i th agent. The sliding surface can be designed as

$$s_i = \dot{q}_i - \dot{q}_{ri} = \dot{q}_i + \alpha \sum_{j \in \mathcal{N}_i} a_{ij}(q_i - q_j) \quad (8)$$

where α is a positive scalar. Note that when $s_i = 0$, (8) is actually the closed-loop system of a consensus algorithm for single integrators. Then if the control torque τ_i can be designed using only local information from neighbors to drive s_i to zero, consensus will be reached as s_i can be treated as a vanishing disturbance to a system that reaches consensus exponentially.

It is generally very challenging to deal with general directed or switching graphs for agents with more complicated dynamics other than single-integrator dynamics. In some cases, the challenge could be overcome by introducing and

updating additional auxiliary variables (often observer-based algorithms) and exchanging these variables between neighbors (see, e.g., (6)). In the algorithm design, the agents might use not only relative physical states between neighbors but also local auxiliary variables from neighbors. While relative physical states could be obtained through sensing, the exchange of auxiliary variables can only be achieved by communication. Hence such generalization is obtained at the price of increased communication between the neighboring agents. Unlike some other algorithms, it is generally impossible to implement the algorithm relying on purely relative sensing between neighbors without the need for communication.

Averaging Algorithms

Existing distributed averaging algorithms are primarily static averaging algorithms based on linear local average iterations or gossip iterations. These algorithms are capable of computing the average of the initial conditions of all agents (or constant signals) in a network. In particular, the linear local-average-iteration algorithms are usually synchronous, where at each iteration each agent repeatedly updates its state to be the average of those of its neighbors. The gossip algorithms are asynchronous, where at each iteration a random pair of agents are selected to exchange their states and update them to be the average of the two. Dynamic averaging algorithms are of significance when there exist time-varying signals. The objective is to compute the average of these time-varying signals in a distributed manner.

Static Averaging

Take a linear local-average-iteration algorithm as an example. The results in this section follow from Tsitsiklis et al. (1986), Jadbabaie et al. (2003), and Olfati-Saber et al. (2007). Let x_i be the information state of agent i . A linear local-average-iteration-type algorithm has the form

Averaging Algorithms and Consensus, Fig. 3 Illustration of distributed averaging of multiple (time-varying) signals. Here A_i denotes agent i and $r_i(t)$ denotes

a (time-varying) signal associated with agent i . Each agent needs to compute the average of all agents' signals but can communicate with only its neighbors

$$x_i[k+1] = \sum_{j \in \mathcal{N}_i[k]} a_{ij}[k] x_j[k], \quad i = 1, \dots, n, \quad (9)$$

where k denotes a communication event, $\mathcal{N}_i[k]$ denotes the neighbor set of agent i , and $a_{ij}[k]$ is the (i, j) entry of the adjacency matrix $\mathcal{A}$ of the graph $\mathcal{G}$ that represents the communication topology at time k , with the additional assumption that $\mathcal{A}$ is row stochastic and $a_{ii}[k] > 0$ for all $i = 1, \dots, n$. Intuitively, the information state of each agent is updated as the weighted average of its current state and the current states of its neighbors at each iteration. Note that an agent maintains its current state if it does not exchange information with other agents at that event instant. In fact, a discretized version of the closed-loop system of (1) using (2) (with a sufficiently small sampling period) takes in the form of (9). The objective here is for all agents to compute the average of their initial states by communicating with only

their neighbors. That is, each $x_i[k]$ approaches $\frac{1}{n} \sum_{j=1}^n x_j[0]$ eventually. To compute the average of multiple constant signals c_i , we could simply set $x_i[0] = c_i$. The algorithm (9) can be written in matrix form as $x[k+1] = \mathcal{A}[k]x[k]$, where x is a column stack vector of all x_i and $\mathcal{A}[k] = [a_{ij}[k]]$ is a row-stochastic matrix.

When the graph $\mathcal{G}$ (and hence the matrix $\mathcal{A}$) is fixed, the convergence of the algorithm (9) can be analyzed by studying the eigenvalues and eigenvectors of the row-stochastic matrix $\mathcal{A}$. Because all diagonal entries of $\mathcal{A}$ are positive, Gershgorin's disc theorem implies that all eigenvalues of $\mathcal{A}$ are either within the open unit disk or at one. When the graph $\mathcal{G}$ is strongly connected, the Perron-Frobenius theorem implies that $\mathcal{A}$ has a simple eigenvalue at one with an associated right eigenvector $\mathbf{1}$ and an associated positive left eigenvector. Hence when $\mathcal{G}$ is strongly connected, it turns out that $\lim_{k \rightarrow \infty} \mathcal{A}^k = \mathbf{1}v^T$, where v^T is a positive left eigenvector of $\mathcal{A}$ associated with

the eigenvalue one and satisfies $v^T \mathbf{1} = 1$. Note that $x[k] = \mathcal{A}^k x[0]$. Hence, each agent's state $x_i[k]$ approaches $v^T x[0]$ eventually. If it can be further ensured that $v = \frac{1}{n} \mathbf{1}$, then averaging is achieved. It can be shown that the agents' states converge to the average of their initial values if and only if the directed graph $\mathcal{G}$ is both strongly connected and balanced or the undirected graph $\mathcal{G}$ is connected. When the graph is switching, the convergence of the algorithm (9) can be analyzed by studying the product of row-stochastic matrices. Such analysis is closely related to Markov chains. It can be shown that the agents' states converge to the average of their initial values if the directed graph $\mathcal{G}$ is balanced at each communication event and strongly connected in a joint manner or the undirected graph $\mathcal{G}$ is jointly connected.

Dynamic Averaging

In a more general setting, there exist n time-varying signals, $r_i(t)$, $i = 1, \dots, n$, which could be an external signal or an output from a dynamical system. Here $r_i(t)$ is available to only agent i and each agent can exchange information with only its neighbors. Each agent maintains a local estimate, denoted by $x_i(t)$, of the average of all the signals $\bar{r}(t) \triangleq \frac{1}{n} \sum_{k=1}^n r_k(t)$. The objective is to design a distributed algorithm for agent i based on $r_i(t)$ and $x_j(t)$, $j \in \mathcal{N}_i(t)$, such that all agents will finally track the average that changes over time. That is, $\|x_i(t) - \bar{r}(t)\|$, $i = 1, \dots, n$, approaches zero eventually. Such a dynamic averaging idea finds applications in distributed sensor fusion with time-varying measurements (Spanos and Murray 2005; Bai et al. 2011b) and distributed estimation and tracking (Yang et al. 2008).

Figure 3 illustrates the dynamic averaging idea. If there exists a central station that can always access the signals of all agents, then it is trivial to compute the average. Unfortunately, in a distributed context, where there does not exist a central station and each agent can only communicate with its local neighbors, it is challenging for each agent to compute the average that changes

over time. While each agent could compute the average of its own and local neighbors' signals, this will not be the average of all signals.

When the signal $r_i(t)$ can be arbitrary but its derivative exists and is bounded almost everywhere, a distributed nonlinear nonsmooth algorithm is designed in Chen et al. (2012) as

$$\begin{aligned} \dot{\phi}_i(t) &= \alpha \sum_{j \in \mathcal{N}_i} \text{sgn}[x_j(t) - x_i(t)] \\ x_i(t) &= \phi_i(t) + r_i(t), \quad i = 1, \dots, n, \end{aligned} \quad (10)$$

where α is a positive scalar, $\mathcal{N}_i$ denotes the neighbor set of agent i , $\text{sgn}(\cdot)$ is the signum function defined componentwise, ϕ_i is the internal state of the estimator with $\phi_i(0) = 0$, and x_i is the estimate of the average $\bar{r}(t)$. Due to the existence of the discontinuous signum function, the solution of (10) is understood in the Filippov sense (Cortes 2008).

The idea behind the algorithm (10) is as follows. First, (10) is designed to ensure that $\sum_{i=1}^n x_i(t) = \sum_{i=1}^n r_i(t)$ holds for all time. Note that $\sum_{i=1}^n x_i(t) = \sum_{i=1}^n \phi_i(t) + \sum_{i=1}^n r_i(t)$. When the graph $\mathcal{G}$ is undirected and $\phi_i(0) = 0$, it follows that $\sum_{i=1}^n \phi_i(t) = \sum_{i=1}^n \phi_i(0) + \alpha \sum_{i=1}^n \sum_{j \in \mathcal{N}_i} \int_0^t \text{sgn}[x_j(\tau) - x_i(\tau)] d\tau = 0$. As a result, $\sum_{i=1}^n x_i(t) = \sum_{i=1}^n r_i(t)$ holds for all time. Second, when $\mathcal{G}$ is connected, if the algorithm (10) guarantees that all estimates x_i approach the same value in *finite time*, then it can be guaranteed that each estimate approaches the average of all signals in finite time.

Summary and Future Research Directions

Averaging algorithms and consensus play an important role in distributed control of networked systems. While there is significant progress in this direction, there are still numerous open problems. For example, it is challenging to achieve averaging when the graph is not balanced. It is generally not clear how to deal with a general directed or switching graph for

nonlinear agents or nonlinear algorithms when the algorithms are based on only interagent physical state coupling without the need for communicating additional auxiliary variables between neighbors. The study of consensus for multiple underactuated agents remains a challenge. Furthermore, when the agents' dynamics are heterogeneous, it is challenging to design consensus algorithms. In addition, in the existing study, it is often assumed that the agents are cooperative. When there exist faulty or malicious agents, the problem becomes more involved.

Abstract

Backstepping is an elegant constructive method, with roots in finite-dimensional control theory, that allows the solution of numerous boundary control and estimation problems for partial differential equations (PDEs). This entry reviews the main ingredients of the method, namely, the concepts of a backstepping invertible transformation, a target system, and the kernel equations. As a basic example, stabilization of a reaction-diffusion equation is explained.

Introduction to PDE Backstepping

In the context of partial differential equations (PDEs), backstepping is a constructive method, originated in the 2000s, mainly used to design boundary controllers and observers, both adaptive and nonadaptive, for numerous classes of systems. Its name comes from the use of the so-called backstepping transformation (a Volterra-type integral transform) as a tool to find feedback control laws and observer gains.

The method has three main ingredients. First, one needs to select a *target system* which verifies the desired properties (most often stability, proven with a Lyapunov function), but still closely resembles the original system. Next, an integral transformation (the backstepping transformation) is posed to map the original plant into the target system in the appropriate functional spaces. The invertibility of the transformation needs to be shown. Finally, using the original

and target systems and the transformation, the *kernel equations* are found. Their solution is the kernel of the integral transformation, which in turn determines the control law. These equations are typically of Goursat type, that is, hyperbolic boundary problems on a triangular domain (with boundary values on two sides and the third side determining the control law), and can usually be proven solvable by transforming the boundary problems to integral equations and then using the method of successive approximations. Tying up all these elements, stability of the closed-loop system is then obtained, based on the stability of the target system which is inherited by the closed-loop system as a result of the structure and well-posedness of the transformation.

These ingredients are always present when using PDE backstepping and are closely connected among themselves. Judiciously choosing the target system will result in solvable kernel equations and an invertible transformation. On the other hand, an ill-chosen target system typically results in kernel equations that cannot be solved or even properly formulated, or a non-invertible transformation.

Next, the rationale of the method is illustrated for a basic case, namely, stabilization of a reaction-diffusion equation.

Reaction-Diffusion Equation

Consider a reaction-diffusion equation

$$u_t = \epsilon u_{xx} + \lambda(x)u, \quad (1)$$

where $u(t, x)$ is the state, for $x \in [0, 1]$ and $t > 0$, with $\epsilon > 0$ and $\lambda(x)$ a continuous function, with boundary conditions

$$u(t, 0) = 0, \quad u(t, 1) = U(t), \quad (2)$$

where $U(t)$ is the actuation variable. These are the so-called Dirichlet-type boundary conditions, but Neumann- ($u_x(t, 0) = 0$) or Robin-type ($u_x(t, 0) = qu(t, 0)$) boundary conditions are also frequently considered. Denote the initial condition $u(0, x)$ as $u_0(x)$.

The system (1)–(2) has an equilibrium, namely, $u \equiv 0$, which is unstable if $\lambda(x)$ is sufficiently large. Thus, the control problem is to design a feedback $U(t)$ such that the origin becomes stable (stability will be made precise by using a Lyapunov approach).

Target System (and Its Stability)

Since the last term in (1) is a potential source of instability, the most natural objective of feedback would be to eliminate it, thus reaching the following target system

$$w_t = \epsilon w_{xx}, \quad (3)$$

that is, a heat equation, with homogeneous Dirichlet boundary conditions

$$w(t, 0) = 0, \quad w(t, 1) = 0. \quad (4)$$

To study the target system stability, consider the $L^2([0, 1])$ space of functions (whose square is integrable in the interval $[0, 1]$), endowed with the norm $\|f\|^2 = \int_0^1 f^2(x)dx$.

Denoting by w_0 the initial condition of (3)–(4), it is well-known that if $w_0 \in L^2([0, 1])$, then $w(t, \cdot) \in L^2([0, 1])$ for each $t > 0$ and, using $\|w(t, \cdot)\|^2$ as a Lyapunov function, the following exponential stability result is verified:

$$\|w(t, \cdot)\|^2 \leq e^{-\alpha t} \|w_0\|^2, \quad (5)$$

where α is a positive number.

Backstepping Transformation (and Its Inverse)

Now, pose the following coordinate transformation

$$w(t, x) = u(t, x) - \int_0^x k(x, \xi)u(t, \xi)d\xi, \quad (6)$$

to map the system (1) into (3). The transformation (6), whose second term is a Volterra-type integral transformation (because of its lower-triangular structure), is the backstepping transformation, and its kernel $k(x, \xi)$ is known as the backstepping kernel. One of the properties

of a Volterra-type transformation is that it is invertible under very mild conditions on the kernel $k(x, \xi)$, for instance, if it is bounded. Assuming for the moment that the kernel verifies this property, then an inverse transformation can be posed as

$$u(t, x) = w(t, x) + \int_0^x l(x, \xi) w(t, \xi) d\xi, \quad (7)$$

where $l(x, y)$ is known as the inverse kernel, and it is also bounded.

It is easy to see that both transformations (6) and (7) map $L^2([0, 1])$ functions into $L^2([0, 1])$ functions. In particular, if u and w are related by the transformations as in (6) and (7), it follows that $\|u\|^2 \leq C_1 \|w\|^2$ and $\|w\|^2 \leq C_2 \|u\|^2$ for some $C_1, C_2 > 0$.

Kernel Equations

The kernel $k(x, \xi)$ verifies the following equation

$$\epsilon k_{xx}(x, \xi) = \epsilon k_{\xi\xi}(x, \xi) + \lambda(\xi)k(x, \xi), \quad (8)$$

with boundary conditions

$$\epsilon k(x, 0) = -0, \quad k(x, x) = -\frac{1}{2\epsilon} \int_0^x \lambda(\xi) d\xi. \quad (9)$$

Equation (8) is a hyperbolic equation of Goursat type. The way to derive (8), along with (9), is by substituting the transformation (6) into the target system (3) and eliminating w . Then, integrating by parts, one gets a weak formulation of (8)–(9).

The PDE (8)–(9) is well-posed and can be solved numerically fast and efficiently. It can be also reduced to an integral equation, by defining $\delta = x + \xi$ and $\eta = x - \xi$, and denoting $G(\delta, \eta) = k(x, \xi) = k\left(\frac{\delta+\eta}{2}, \frac{\delta-\eta}{2}\right)$. Then, $G(\delta, \eta)$ verifies the following equation:

$$4\epsilon G_{\delta\eta} = \lambda\left(\frac{\delta-\eta}{2}\right) G(\delta, \eta), \quad (10)$$

with boundary conditions

$$G(\delta, \delta) = 0,$$

$$G(\delta, 0) = -\frac{1}{4\epsilon} \int_0^\delta \lambda\left(\frac{\tau}{2}\right) d\tau. \quad (11)$$

Equation (10) for G can be integrated, yielding an integral equation for G

$$\begin{aligned} G(\delta, \eta) = & -\frac{1}{4\epsilon} \int_\eta^\delta \lambda\left(\frac{\tau}{2}\right) d\tau \\ & + \frac{1}{4\epsilon} \int_\eta^\delta \int_0^\eta \lambda\left(\frac{\tau-s}{2}\right) G(\tau, s) ds d\tau. \end{aligned} \quad (12)$$

The method of successive approximations can be used to solve (12). Define $G_0(\delta, \eta) = -\frac{1}{4\epsilon} \int_\eta^\delta \lambda\left(\frac{\tau}{2}\right) d\tau$ and, for $n \geq 1$,

$$\begin{aligned} G_n(\delta, \eta) = & G_{n-1}(\delta, \eta) \\ & + \frac{1}{4\epsilon} \int_\eta^\delta \int_0^\eta \lambda\left(\frac{\tau-s}{2}\right) G_{n-1}(\tau, s) ds d\tau. \end{aligned} \quad (13)$$

Then it can be shown that $G(\delta, \eta) = \lim_{n \rightarrow \infty} G_n(\delta, \eta)$. The function G_n can be computed recursively and used to approximate symbolically G and thus k . This procedure shows that (8)–(9) is well-posed (the limit always exists) and its solution k is continuous (and thus invertible). In fact, for constant λ , the exact solution is

$$k(x, \xi) = -\frac{\lambda}{\epsilon} \xi \frac{I_1\left(\sqrt{\frac{\lambda}{\epsilon}}(x^2 - \xi^2)\right)}{\sqrt{\frac{\lambda}{\epsilon}}(x^2 - \xi^2)},$$

where I_1 is the first-order modified Bessel function of the first kind.

Feedback Law and Closed-Loop System Stability

The feedback U in (2) is what makes the original system behave like the target system and can be found by setting $x = 1$ in the backstepping transformation (6) and using the boundary conditions (2) and (4), which yields the feedback law

$$U(t) = \int_0^1 k(1, \xi) u(t, \xi) d\xi. \quad (14)$$

Finally, using (5) and the properties of the transformations (6) and (7), one can obtain

$$\begin{aligned} \|u(t)\|^2 &\leq C_2 \|w(t)\|^2 \leq C_2 e^{-\alpha t} \|w_0\|^2 \\ &\leq C_1 C_2 e^{-\alpha t} \|u_0\|^2, \end{aligned} \quad (15)$$

thus showing exponential stability for the origin of the system (1)–(2).

Summary and Future Directions

Backstepping as a method for control of PDEs is a fairly recent development, and the area of control of PDEs is in itself an emerging and active area of research with great potential in many engineering applications that cannot be modeled solely by finite-dimensional dynamics. To learn more about the basics, we recommend the book (Anfinsen and Aamo 2019) which contains a didactic exposition of the initial backstepping results, providing details to design controllers and observers for parabolic equations and others. While we only dealt with the basic theoretical developments, the subject on the other hand has been steadily growing in the last decade. The technical literature now contains a wealth of results in application areas as diverse as oil pipe flows, battery health estimation, thermoacoustics, multi-phase flows, 3-D printing, or traffic control, among others, with hundreds of additional references. To name a few, we would like to mention several books written on the subject which include interesting recent and forth coming developments in topics such as flow control (Krstic 2009), adaptive control of parabolic PDEs (Krstic and Smyshlyaev 2008), adaptive control of hyperbolic PDEs (Smyshlyaev and Krstic 2010), or delays (Vazquez and Krstic 2008).

Backward Stochastic Differential Equations and Related Control Problems

Shige Peng

Shandong University, Jinan, Shandong Province, China

Abstract

A conditional expectation of the form $Y_t = E[\xi + \int_t^T f_s ds | \mathcal{F}_t]$ is regarded as a simple and typical example of backward stochastic differential equation (abbreviated by BSDE). BSDEs are widely applied to formulate and solve problems related to stochastic optimal control, stochastic games, and stochastic valuation.

Keywords

Brownian motion · Feynman-Kac formula · Lipschitz condition · Optimal stopping

Synonyms

BSDE

Definition

A typical real valued backward stochastic differential equation defined on a time interval $[0, T]$ and driven by a d -dim. Brownian motion B is

$$\begin{cases} dY_t = -f(t, Y_t, Z_t)dt + Z_t dB_t, \\ Y_T = \xi, \end{cases}$$

or its integral form

$$Y_t = \xi + \int_t^T f(s, \omega, Y_s, Z_s)ds - \int_t^T Z_s dB_s, \quad (1)$$

where ξ is a given random variable depending on the (canonical) Brownian path $B_t(\omega) = \omega(t)$ on $[0, T]$, $f(t, \omega, y, z)$ is a given function of the time t , the Brownian path ω on $[0, t]$, and the pair of variables $(y, z) \in \mathbb{R}^m \times \mathbb{R}^{m \times d}$. A solution of this BSDE is a pair of stochastic processes (Y_t, Z_t) , the solution of the above equation, on $[0, T]$ satisfying the following constraint: for each t , the value of $Y_t(\omega)$, $Z_t(\omega)$ depends only on the Brownian path ω on $[0, t]$. Notice that, because of this constraint, the extra freedom Z_t is needed. For simplicity we set $d = m = 1$.

Often square-integrable conditions for ξ and f and Lipschitz condition for f with respect to (y, z) are assumed under which there exists a unique square-integrable solution (Y_t, Z_t) on $[0, T]$ (existence and uniqueness theorem of BSDE). We can also consider a multidimensional process Y and/or a multidimensional Brownian motion B , L^p -integrable conditions ($p \geq 1$) for ξ and f , as well as local Lipschitz conditions of f with respect to (y, z) . If Y_t is real valued, we often call the equation a real valued BSDE.

We compare this BSDE with the classical stochastic differential equation (SDE):

$$dX_s = \sigma(X_s)dB_s + b(X_s)ds$$

with given initial condition $X_s|_{s=0} = x \in \mathbb{R}^n$. Its integral form is

$$\begin{aligned} X_t(\omega) &= x + \int_0^t \sigma(X_s(\omega))dB_s(\omega) \\ &\quad + \int_0^t b(X_s(\omega))ds. \end{aligned} \quad (2)$$

Linear backward stochastic differential equation was firstly introduced (Bismut 1973) in stochastic optimal control problems to solve the adjoint equation in the stochastic maximum principle of Pontryagin's type. The above existence and uniqueness theorem was obtained by Pardoux and Peng (1990). In the research domain of economics, this type of 1-dimensional BSDE was also independently derived by Duffie and Epstein (1992). Comparison theorem of BSDE was obtained in Peng (1992) and improved in El Karoui et al. (1997a). Nonlinear Feynman-Kac formula was obtained in Peng (1991, 1992) and improved in Pardoux and Peng (1992). BSDE is applied as a nonlinear Black-Scholes option pricing formula in finance. This formulation was given in El Karoui et al. (1997b). We refer to a recent survey in Peng (2010) for more details.

Hedging and Risk Measuring in Finance

Let us consider the following hedging problem in a financial market with a typical model of continuous time asset price: the basic securities consist of two assets, a riskless one called bond, and a risky security called stock. Their prices are governed by $dP_t^0 = P_t^0 r dt$, for the bond, and

$$dP_t = P_t[bdt + \sigma dB_t], \quad \text{for the stock.}$$

Here we only consider the situation where the volatility rate $\sigma > 0$. The case of multidimensional stocks with degenerate volatility matrix σ can be treated by constrained BSDE. Assume that a small investor whose investment behavior cannot affect market prices and who invests at time $t \in [0, T]$ the amount π_t of his or her wealth Y_t in the security and π_t^0 in the bond, thus $Y_t = \pi_t^0 + \pi_t$. If his investment strategy is self-financing, then we

have $dY_t = \pi_t^0 dP_t^0 / P_t^0 + \pi_t dP_t / P_t$, thus

$$dY_t = (rY_t + \pi_t \sigma \theta) dt + \pi_t \sigma dB_t,$$

where $\theta = \sigma^{-1}(b - r)$. A strategy $(Y_t, \pi_t)_{t \in [0, T]}$ is said to be feasible if $Y_t \geq 0, t \in [0, T]$. A European path-dependent contingent claim settled at time T is a given nonnegative function of path $\xi = \xi((P_t)_{t \in [0, T]})$. A feasible strategy (Y, π) is called a hedging strategy against a contingent claim ξ at the maturity T if it satisfies

$$dY_t = (rY_t + \pi_t \sigma \theta) dt + \pi_t \sigma dB_t, \quad Y_T = \xi.$$

This problem can be regarded as finding a stochastic control π and an initial condition Y_0 such that the final state replicates the contingent claim ξ , i.e., $Y_T = \xi$. This type of replications is also called “exact controllability” in terms of stochastic control (see Peng 2005 for more general results).

Observe that $(Y, \pi \sigma)$ is the solution of the above BSDE. It is called a superhedging strategy if there exists an increasing process K_t , often called an accumulated consumption process, such that

$$dY_t = (rY_t + \pi_t \sigma \theta) dt + \pi_t \sigma dB_t - dK_t, \quad Y_T = \xi.$$

This type of strategies is often applied in a constrained market in which certain constraint $(Y_t, \pi_t) \in \Gamma$ is imposed. In fact a real market has many frictions and constraints. An example is the common case where interest rate R for borrowing money is higher than the bond rate r . The above equation for the hedging strategy becomes

$$dY_t = [rY_t + \pi_t \sigma \theta - (R - r)(\pi_t - Y_t)^+] dt + \pi_t \sigma dB_t, \quad Y_T = \xi,$$

where $[\alpha]^+ = \max\{\alpha, 0\}$. A short selling constraint $\pi_t \geq 0$ is also a typical requirement in markets. The method of constrained BSDE can be applied to this type of problems. BSDE theory provides powerful tools to the robust pricing and risk measures for contingent claims (see El Karoui et al. 1997a). For the dynamic risk

measure under Brownian filtration, see Rosazza Gianin (2006), Peng (2004), Barrieu and El Karoui (2005), Hu et al. (2005), and Delbaen et al. (2010).

Comparison Theorem

The comparison theorem, for a real valued BSDE, tells us that, if (Y_t, Z_t) and $(\bar{Y}_t, \bar{Z}_t)$ are two solutions of BSDE (1) with terminal condition $Y_T = \xi, \bar{Y}_T = \bar{\xi}$ such that $\xi(\omega) \geq \bar{\xi}(\omega), \omega \in \Omega$, then one has $Y_t \geq \bar{Y}_t$. This theorem holds if f and $\bar{\xi}, \bar{\xi}$ satisfy the abovementioned L^2 -integrability condition and f is a Lipschitz function in (y, z) . This theorem plays the same important role as the maximum principle in PDE theory. The theorem also has several very interesting generalizations (see Buckdahn et al. 2000).

Stochastic Optimization and Two-Person Zero-Sum Stochastic Games

An important point of view is to regard an expectation value as a solution of a special type of BSDE. Consider an optimal control problem

$$\min_u J(u) : \quad J(u) = E \left[\int_0^T l(X_s, u_s) ds + h(X_T) \right].$$

Here the state process X is controlled by the control process u_t which is valued in a control (compact) domain U through the following d -dimensional SDE

$$dX_s = b(X_s, u_s) ds + \sigma(X_s) dB_s$$

defined in a Wiener probability space $(\Omega, \mathcal{F}, P)$ with the Brownian motion $B_t(\omega) = \omega(t)$ which is the canonical process. Here we only discuss the case $\sigma \equiv I_d$ for simplicity. Observe that in fact the expected value $J(u)$ is $Y_0^u = E[Y_0^u]$, where Y_t^u solves the BSDE

$$Y_t^u = h(X_T) + \int_t^T l(X_s, u_s) ds - \int_t^T Z_s^u dB_s.$$

From Girsanov transformation, under the probability measure $\tilde{P}$ defined by

$$\frac{d\tilde{P}}{dP}|_T = \exp \left\{ \int_0^T b(X_s, u_s) dB_s - \frac{1}{2} \int_0^T |b(X_s, u_s, v_s)|^2 ds \right\}$$

X_t is a Brownian motion, and the above BSDE is changed to

$$Y_t^u = h(X_T) + \int_t^T [l(X_s, u_s) + \langle Z_s^u, b(X_s, u_s) \rangle] ds - \int_t^T Z_s^u dX_s,$$

where $\langle \cdot, \cdot \rangle$ is the Euclidean scalar product in $\mathbb{R}^d$. Notice that P and $\tilde{P}$ are absolutely continuous with each other. Compare this BSDE with the following one:

$$\hat{Y}_t = h(X_T) + \int_t^T H(X_s, \hat{Z}_s) ds - \int_t^T \hat{Z}_s dX_s, \quad (3)$$

where $H(x, z) := \inf_{u \in U} \{l(x, u) + \langle z, b(x, u) \rangle\}$. It is a direct consequence of the comparison theorem of BSDE that $\hat{Y}_0 \leq Y_0^u = J(u)$, for any admissible control u_t . Moreover, one can find a feedback control $\hat{u}$ such that $\hat{Y}_0 = J(\hat{u})$.

The above BSDE method has been introduced to solve the following two-person zero-sum game (Hamadène and Lepeltier 1995):

$$\begin{aligned} & \max_v \min_u J(u, v), \quad J(u, v) \\ & = E \left[\int_0^T l(X_s, u_s, v_s) ds + h(X_T) \right] \end{aligned}$$

with

$$dX_s = b(X_s, u_s, v_s) ds + dB_s,$$

where (u_s, v_s) is formulated as above with compact control domains $u_s \in U$ and $v_s \in V$. In this case the equilibrium of the game exists if the following Isaac condition is satisfied:

$$\begin{aligned} H(x, z) &:= \max_{v \in V} \inf_{u \in U} \{l(x, u, v) + \langle z, b(x, u, v) \rangle\} \\ &= \inf_{u \in U} \max_{v \in V} \{l(x, u, v) + \langle z, b(x, u, v) \rangle\}, \end{aligned}$$

and the equilibrium is also obtained through a BSDE (3) defined above.

Nonlinear Feynman-Kac Formula

A very interesting situation is when $f = g(X_t, y, z)$ and $Y_T = \varphi(X_T)$ in BSDE (1). In this case we have the following relation, called “nonlinear Feynman-Kac formula,”

$$Y_t = u(t, X_t), \quad Z_t = \sigma^T(X_t) \nabla u(t, X_t)$$

where $u = u(t, x)$ is the solution of the following quasilinear parabolic PDE:

$$\partial_t u + \mathcal{L}u + g(x, u, \sigma^T \nabla u) = 0, \quad (4)$$

$$u(x, T) = \varphi(x), \quad (5)$$

where $\mathcal{L}$ is the following, possibly degenerate, elliptic operator:

$$\begin{aligned} \mathcal{L}\varphi(x) &= \frac{1}{2} \sum_{i,j=1}^d a_{ij}(x) \partial_{x_i x_j}^2 \varphi(x) \\ &+ \sum_{i=1}^d b_i(x) \partial_{x_i} \varphi(x), \quad a(x) = \sigma(x) \sigma^T(x). \end{aligned}$$

Nonlinear Feynman-Kac formula can be used to solve a nonlinear PDE of form (4) to (5) by a BSDE (1) coupled with an SDE (2).

A general principle is, once we solve a BSDE driven by a Markov process X for which the terminal condition Y_T at time T depends only on X_T and the generator $f(t, \omega, y, z)$ also depends on the state X_t at each time t , then the corresponding solution of the BSDE is also state dependent, namely, $Y_t = u(t, X_t)$, where u is the solution of the corresponding quasilinear PDE. Once Y_T and g are path functions of X , then the solution of the BSDE becomes also path dependent. In this sense, we can say that the PDE is in fact a “state-dependent BSDE,” and BSDE gives us a new generalization of “path-dependent PDE” of parabolic and/or elliptic types. This principle was illustrated in Peng (2010) for both quasilinear and fully nonlinear situations.

Observe that BSDE (1) and forward SDE (2) are only partially coupled. A fully coupled system of SDE and BSDE is called a forward-backward stochastic differential equation (FBSDE). It has the following form:

$$\begin{aligned} dX_t &= b(t, X_t, Y_t, Z_t)dt + \sigma(t, X_t, Y_t, Z_t)dB_t, \\ X_0 &= x \in \mathbb{R}^n, \\ -dY_t &= f(t, X_t, Y_t, Z_t)dt - Z_t dB_t, \quad Y_T = \varphi(X_T). \end{aligned}$$

In general the Lipschitz assumptions for b, σ, f , and φ w. r. t. (x, y, z) are not enough. Then Ma et al. (1994) have proposed a four-step scheme method of FBSDE for the nondegenerate Markovian case with σ independent of Z . For the case $\dim(x) = \dim(y) = n$, Hu and Peng (1995) proposed a new type of monotonicity condition. This method does not need to assume the coefficients to be deterministic. Peng and Wu (1999) have weakened the monotonicity condition. Observe that in the case where $b = \nabla_y H(x, y, z)$, $\sigma = \nabla_z H(x, y, z)$, and $f = \nabla_x H(x, y, z)$, for a given real valued function H convex in x concave in (y, z) , the above FBSDE is called the stochastic Hamilton equation associated to a stochastic optimal control problem. We also refer to the book of Ma and Yong (1999) for a systematic exposition on this subject. For time-symmetric forward-backward stochastic differential equations and its relation with stochastic optimality, see Peng and Shi (2003) and Han et al. (2010).

Reflected BSDE and Optimal Stopping

If (Y, Z) solves the BSDE

$$dY_s = -g(s, Y_s, Z_s)ds + Z_s dB_s - dK_s, \quad Y_T = \xi, \quad (6)$$

where K is a càdlàg and increasing process with $K_0 = 0$ and $K_t \in L_P^2(\mathcal{F}_t)$, then Y or (Y, Z, K) is called a *supersolution* of the BSDE, or *g-supersolution*. This notion is often used for constrained BSDEs. A typical situation is as follows: for a given continuous adapted process $(L_t)_{t \in [0, T]}$, find a smallest g -supersolution

(Y, Z, K) such that $Y_t \geq L_t$. This problem was initiated in El Karoui et al. (1997b). It is proved that this problem is equivalent to finding a triple (Y, Z, K) satisfying (4) and the following reflecting condition of Skorohod type:

$$Y_s \geq L_s, \quad \int_0^T (Y_s - L_s) dK_s = 0. \quad (7)$$

In fact $\tau^* := \inf\{t \in [0, T] : K_t > 0\}$ is the optimal stopping time associated to this BSDE. A well-known example is the pricing of American option.

Moreover, a new type of nonlinear Feynman-Kac formula was introduced: if all coefficients are given as in the formulation of the above nonlinear Feynman-Kac formula and $L_s = \Phi(X_s)$ where Φ satisfies the same condition as φ , then we have $Y_s = u(s, X_s)$, where $u = u(t, x)$ is the solution of the following variational inequality:

$$\begin{aligned} \min\{\partial_t u + \mathcal{L}u + g(x, u, \sigma^* Du), u - \Phi\} \\ = 0, \quad (t, x) \in [0, T] \times \mathbb{R}^n, \quad (8) \end{aligned}$$

with terminal condition $u|_{t=T} = \varphi$. They also demonstrated that this reflected BSDE is a powerful tool to deal with contingent claims of American types in a financial market with constraints.

BSDE reflected within two barriers, a lower one L and an upper one U , was first investigated by Cvitanic and Karatzas (1996) where a type of nonlinear Dynkin games was formulated for a two-player model with zero-sum utility and each player chooses his own optimal exit time.

Stochastic optimal switching problems can be also solved by new types of oblique-reflected BSDEs.

A more general case of constrained BSDE is to find the smallest g -supersolution (Y, Z, K) with constraint $(Y_t, Z_t) \in \Gamma_t$ where, for each $t \in [0, T]$, Γ_t (El Karoui and Quenez 1995; Cvitanic and Karatzas 1993; El Karoui et al. 1997a) for the problem of superhedging in a market with convex constrained portfolios (Cvitanic et al. 1998). The case with an arbitrary closed constraint was proved in Peng (1999).

Backward Stochastic Semigroup and g -Expectations

Let $\mathcal{E}_{t,T}^g[\xi] = Y_t$ where Y is the solution of BSDE (1). $(\mathcal{E}_{t,T}^g[\cdot])_{0 \leq t \leq T < \infty}$ has the (backward) semigroup property (Peng 1997)

$$\begin{aligned}\mathcal{E}_{s,t}^g[\mathcal{E}_{t,T}^g[\xi]] &= \mathcal{E}_{s,T}^g[\xi], \quad \mathcal{E}_{T,T}^g[\xi] \\ &= \xi, \quad 0 \leq s \leq t \leq T.\end{aligned}$$

For a real valued BSDE, by the comparison theorem, the semigroup is monotone: $\mathcal{E}_{t,T}^g[\xi] \geq \mathcal{E}_{t,T}^g[\tilde{\xi}]$, if $\xi \geq \tilde{\xi}$. If moreover $g|_{z=0} = 0$, then the semigroup is constant preserving: $\mathcal{E}_{t,T}^g[c] \equiv c$. Thus the semigroup forms in fact a nonlinear expectation called g -expectation (since this nonlinear expectation is totally determined by the generator g).

This notion allows us to establish a nonlinear g -martingale theory, e.g., g -supermartingale decomposition theorem. Peng (1999) claims that, if Y is a square-integrable càdlàg g -supermartingale, then it has the unique decomposition: there exists a unique predictable, increasing, and càdlàg process A such that Y solves

$$-dY_t = g(t, Y_t, Z_t)dt + dA_t - Z_t dB_t.$$

A theoretically challenging and practically important problem is as follows: given an abstract family of expectations $(\mathcal{E}_{s,t}[\cdot])_{s \leq t}$ satisfying the same backward semigroup properties as these of g -expectation, can we find a function g such that $\mathcal{E}_{s,t} \equiv \mathcal{E}_{s,t}^g$? Coquet, Hu et al. (2005) proved that if $\mathcal{E}$ is dominated by g_μ -expectation with $g_\mu(z) = \mu|z|$ for a large enough constant $\mu > 0$, then there exists a unique function $g = g(t, \omega, z)$ satisfying μ -Lipschitz condition such that $(\mathcal{E}_{s,t}[\cdot])_{s \leq t}$ is in fact a g -expectation. For a concave dynamic expectation with an assumption much weaker than the above domination condition, we can still find a function $g = g(t, z)$ with possibly singular values (Delbaen et al. 2010). For the case without the assumption of constant preservation, see Peng (2005). In practice, the above criterion is very useful to test whether a dynamic pricing mechanism of contingent contracts can be represented through a concrete function g .

A serious challenging problem in the stochastic control theory is as follows: it is based on a given probability space $(\Omega, \mathcal{F}, P)$. But in most practical situations, it is far from being true. In many risky situations, it is necessary to consider the uncertainty of the probability measures themselves, e.g., $\{P_\theta\}_{\theta \in \Theta}$, namely, the well-known Knightian uncertainty (Knight 1921). A new framework of G -expectation space $(\Omega, \mathcal{H}, \hat{\mathbb{E}})$ and the corresponding random and stochastic analysis (Itô's analysis) is introduced (see Peng 2007, 2010 and Sonner et al. 2012) to replace the probability framework $(\Omega, \mathcal{F}, P)$. g -expectation is a special and typical case in this new theory.

Abstract

Basic principles for the development of computational methods for the analysis and design of linear time-invariant systems are discussed. These have been used in the design of the subroutine library SLICOT. The principles are illustrated on the basis of a method to check the controllability of a linear system.

Keywords

Accuracy · Basic numerical methods · Benchmarking · Controllability · Documentation and implementation standards · Efficiency · Software design

Introduction

Basic numerical methods for the analysis and design of dynamical systems are at the heart of most techniques in systems and control theory that are used to describe, control, or optimize industrial and economical processes. There are many methods available for all the different tasks in systems and control, but even though most of these methods are based on sound theoretical principles, many of them still fail when applied to real-life problems. The reasons for this may be quite diverse, such as the fact that the system dimensions are very large, that the underlying problem is very sensitive to small changes in the data, or that the method lacks numerical robustness when implemented in a finite precision environment.

To overcome such failures, major efforts have been made in the last few decades to develop robust, well-implemented, and standardized software packages for computer-aided control systems design (Grübel 1983; Nag Slicot 1990; Wieslander 1977). Following the standards of modern software design, such packages should consist of numerically robust routines with known performance in terms of reliability and efficiency that can be used to form the basis of more complex control methods. Also to avoid duplication and to achieve efficiency and portability to different computational environments, it is essential to make maximal use of the established standard packages that are available for numerical computations, e.g., the **Basic Linear Algebra Subroutines (BLAS)** (Dongarra et al. 1990) or the **Linear Algebra Packages (LAPACK)** (Anderson et al. 1992). On the basis of such standard packages, the next layer of more complex control methods can then be built in a robust way.

In the late 1980s, a working group was created in Europe to coordinate efforts and integrate and extend the earlier software developments in systems and control. Thanks to the support of the European Union, this eventually led to the development of the **Subroutine Library in Control Theory (SLICOT)** (Benner et al. 1999; SLICOT 2012). This library contains most of the basic computational methods for control systems design of linear time-invariant control systems.

An important feature of this and similar kind of subroutine libraries is that the development of further higher level methods is not restricted by specific requirements of the languages or data structures used and that the routines can be easily incorporated within other more user-friendly software systems (Gomez et al. 1997; MATLAB 2013). Usually, this *low-level reusability* can only be achieved by using a general-purpose programming language like C or Fortran.

We cannot present all the features of the SLICOT library here. Instead, we discuss its general philosophy in section “[The Control Subroutine Library SLICOT](#)” and illustrate these concepts in section “[An Illustration](#)” using one specific task,

namely, checking the controllability of a system. We refer to SLICOT (2012) for more details on SLICOT and to Varga (2004) for a general discussion on numerical software for systems and control.

The Control Subroutine Library SLICOT

When designing a subroutine library of basic algorithms, one should make sure that it satisfies certain basic requirements and that it follows a strict standardization in implementation and documentation. It should also contain standardized test sets that can be used for benchmarking, and it should provide means for maintenance and portability to new computing environments. The subroutine library SLICOT was designed to satisfy the following basic recommendations that are typically expected in this context (Benner et al. 1999).

Robustness: A subroutine must either return reliable results or it must return an error or warning indicator, if the problem has not been well posed or if the problem does not fall in the class to which the algorithm is applicable or if the problem is too ill-conditioned to be solved in a particular computing environment.

Numerical stability and accuracy: Subroutines are supposed to return results that are as good as can be expected when working at a given precision. They also should provide an option to return a parameter estimating the accuracy actually achieved.

Efficiency: An algorithm should never be chosen for its speed if it fails to meet the usual standards of robustness, numerical stability, and accuracy, as described above. Efficiency must be evaluated, e.g., in terms of the number of floating-point operations, the memory requirements, or the number and cost of iterations to be performed.

Modern computer architectures: The requirements of modern computer architectures must be taken into account, such as shared or distributed memory parallel processors,

which are the standard environments of today. The differences in the various architectures may imply different choices of algorithms.

Comprehensive functional coverage: The routines of the library should solve control systems relevant computational problems and try to cover a comprehensive set of routines to make it functional for a wide range of users. The SLICOT library covers most of the numerical linear algebra methods needed in systems analysis and synthesis problems for standard and generalized state space models, such as Lyapunov, Sylvester, and Riccati equation solvers, transfer matrix factorizations, similarity and equivalence transformations, structure exploiting algorithms, and condition number estimators.

The implementation of subroutines for a library should be highly standardized, and it should be accompanied by a well-written online documentation as well as a user manual (see, e.g., standard Denham and Benson 1981; Working Group Software 1996) which is compatible with that of the LAPACK library (Anderson et al. 1992). Although such highly restricted standards often put a heavy burden on the programmer, it has been observed that it has a high importance for the reusability of software and it also has turned out to be a very valuable tool in teaching students how to implement algorithms in the context of their studies.

Benchmarking

In the validation of numerical software, it is extremely important to be able to test the correctness of the implementation as well as the performance of the method, which is one of the major steps in the construction of a software library. To achieve this, one needs a standardized set of benchmark examples that allows an evaluation of a method with respect to correctness, accuracy, and efficiency and to analyze the behavior of the method in extreme situations, i.e., on problems where the limit of the possible accuracy is reached. In the context of basic systems and control methods, several such

benchmark collections have been developed (see, e.g., Benner et al. 1997; Frederick 1998, or <http://www.slicot.org/index.php?site=benchmarks>).

Maintenance, Open Access, and Archives

It is a major challenge to maintain a well-developed library accessible and usable over time when computer architectures and operating systems are changing rapidly, while keeping the library open for access to the user community. This usually requires financial resources that either have to be provided by public funding or by licensing the commercial use.

In the SLICOT library, this challenge has been addressed by the formation of the Niconet Association (<http://www.niconet-ev.info/en/>) which provides the current versions of the codes and all the documentations. Those of Release 4.5 are available under the GNU General Public License or from the archives of <http://www.slicot.org/>.

An Illustration

To give an illustration for the development of a basic control system routine, we consider the specific problem of checking controllability of a linear time-invariant control system. A linear time-invariant control problem has the form

$$\frac{dx}{dt} = Ax + Bu, \quad t \in [t_0, \infty) \quad (1)$$

Here x denotes the *state* and u the *input function*, and the system matrices are typically of the form $A \in \mathbb{R}^{n,n}$, $B \in \mathbb{R}^{n,m}$.

One of the most important topics in control is the question whether by an appropriate choice of input function $u(t)$ we can control the system from an arbitrary state to the null state. This property, called *controllability*, can be characterized by one of the following equivalent conditions (see Paige 1981).

Theorem 1 *The following are equivalent:*

- (i) *System (1) is controllable.*
- (ii) *Rank $[B, AB, A^2B, \dots, A^{n-1}B] = n$.*
- (iii) *Rank $[B, A - \lambda I] = n \quad \forall \lambda \in \mathbb{C}$.*

- (iv) *$\exists F$ such that A and $A + BF$ have no common eigenvalues.*

The conditions of Theorem 1 are nice for theoretical purposes, but none of them is really adequate for the implementation of an algorithm that satisfies the requirements described in the previous section. Condition (ii) creates difficulties because the controllability matrix $K = [B, AB, A^2B, \dots, A^{n-1}B]$ will be highly corrupted by roundoff errors. Condition (iii) can simply not be checked in finite time. However, it is sufficient to check this condition only for the eigenvalues of A , but this is extremely expensive. And finally, condition (iv) will almost always give disjoint spectra between A and $A + BF$ since the computation of eigenvalues is sensitive to roundoff.

To devise numerical procedures, one often resorts to the computation of canonical or condensed forms of the underlying system. To obtain such a form one employs controllability preserving linear transformations $x \mapsto Px$, $u \mapsto Qu$ with nonsingular matrices $P \in \mathbb{R}^{n,n}$, $Q \in \mathbb{R}^{m,m}$. The canonical form under these transformations is the Luenberger form (see Luenberger 1967). This form allows to check the controllability using the above criterion (iii) by simple inspection of the condensed matrices. This is ideal from a theoretical point of view but is very sensitive to small perturbations in the data, in particular because the transformation matrices may have arbitrary large norm, which may lead to large errors.

For the implementation as robust numerical software one uses instead transformations with real orthogonal matrices P, Q that can be implemented in a backward stable manner, i.e., the resulting backward error is bounded by a small constant times the unit roundoff u of the finite precision arithmetic, and employs for reliable rank determinations the well-known singular value decomposition (SVD) (see, e.g., Golub and Van Loan 1996).

Theorem 2 (Singular value decomposition) *Given $A \in \mathbb{R}^{n,m}$, then there exist orthogonal matrices U, V with $U \in \mathbb{R}^{n,n}$, $V \in \mathbb{R}^{m,m}$,*

such that $A = U\Sigma V^T$ and $\Sigma \in \mathbb{R}^{n,m}$ is quasi-diagonal, i.e.,

$$\Sigma = \begin{bmatrix} \Sigma_r & 0 \\ 0 & 0 \end{bmatrix} \text{ where } \Sigma_r = \begin{bmatrix} \sigma_1 & & \\ & \ddots & \\ & & \sigma_r \end{bmatrix},$$

and the nonzero singular values σ_i are ordered as $\sigma_1 \geq \sigma_2 \geq \dots \geq \sigma_r > 0$.

The SVD presents the *best* way to determine (numerical) ranks of matrices in finite precision arithmetic by counting the number of singular values satisfying $\sigma_j \geq \mathbf{u}\sigma_1$ and by putting those for which $\sigma_j < \mathbf{u}\sigma_1$ equal to zero. The computational method for the SVD is well established and analyzed, and it has been implemented in the LAPACK routine SGESVD (see <http://www.netlib.org/lapack/>). A faster but less reliable alternative to compute the numerical rank of a matrix A is its QR factorization with pivoting (see, e.g., Golub and Van Loan 1996).

Theorem 3 (QRE decomposition) Given $A \in \mathbb{R}^{n,m}$, then there exists an orthogonal matrix $Q \in \mathbb{R}^{n,n}$ and a permutation $E \in \mathbb{R}^{m,m}$, such that $A = QRE^T$ and $R \in \mathbb{R}^{n,m}$ is trapezoidal, i.e.,

$$R = \begin{bmatrix} r_{11} & \dots & r_{1l} & \dots & r_{1m} \\ & \ddots & & & \vdots \\ & & r_{ll} & \dots & r_{lm} \\ 0 & & & 0 & \end{bmatrix}.$$

and the nonzero diagonal entries r_{ii} are ordered as $r_{11} \geq \dots \geq r_{ll} > 0$.

The (numerical) rank in this case is again obtained by counting the diagonal elements $r_{ii} \geq \mathbf{u}r_{11}$.

One can use such orthogonal transformations to construct the controllability staircase form (see Van Dooren 1981).

Theorem 4 (Staircase form) Given matrices $A \in \mathbb{R}^{n,n}$, $B \in \mathbb{R}^{n,m}$, then there exist orthogonal matrices P, Q with $P \in \mathbb{R}^{n,n}$, $Q \in \mathbb{R}^{m,m}$, so that

$$\begin{aligned} PAP^T &= \left[\begin{array}{cccc|c} A_{11} & \dots & \dots & A_{1,r-1} & A_{1,r} \\ A_{21} & \ddots & & \vdots & \vdots \\ & \ddots & & \vdots & \vdots \\ & & A_{r-1,r-2} & A_{r-1,r-1} & A_{r-1,r} \\ 0 & \dots & 0 & 0 & A_{rr} \end{array} \right] \begin{matrix} n_1 \\ n_2 \\ \vdots \\ n_{r-1} \\ n_r \end{matrix} \\ PBQ &= \left[\begin{array}{cc} B_1 & 0 \\ 0 & 0 \\ \vdots & \vdots \\ \vdots & \vdots \\ 0 & 0 \end{array} \right] \begin{matrix} n_1 \\ n_2 \\ \vdots \\ \vdots \\ n_r \\ n_1 \quad m - n_1 \end{matrix} \end{aligned} \quad (2)$$

where $n_1 \geq n_2 \geq \dots \geq n_{r-1} \geq n_r \geq 0$, $n_{r-1} > 0$, $A_{i,i-1} = [\Sigma_{i,i-1} \ 0]$, with nonsingular blocks $\Sigma_{i,i-1} \in \mathbb{R}^{n_i, n_i}$ and $B_1 \in \mathbb{R}^{n_1, n_1}$.

Notice that when using the reduced pair in condition (iii) of Theorem 1, the controllability condition is just $n_r = 0$, which is simply checked by inspection. A numerically stable algorithm to compute the staircase form of Theorem 4 is given below. It is based on the use of the singular value decomposition, but one could also have used instead the QR decomposition with column pivoting.

Staircase Algorithm

Input: $A \in \mathbb{R}^{n,n}$, $B \in \mathbb{R}^{n,m}$

Output: PAP^T, PBQ in the form (2), P, Q orthogonal

Step 0: Perform an SVD $B = U_B \begin{bmatrix} \Sigma_B & 0 \\ 0 & 0 \end{bmatrix} V_B^T$ with nonsingular and diagonal $\Sigma_B \in \mathbb{R}^{n_1, n_1}$. Set $P := U_B^T$, $Q := V_B$, so that

$$A := U_B^T A U_B = \begin{bmatrix} A_{11} & A_{12} \\ A_{21} & A_{22} \end{bmatrix},$$

$$B := U_B^T B V_B = \begin{bmatrix} \Sigma_B & 0 \\ 0 & 0 \end{bmatrix}$$

with A_{11} of size $n_1 \times n_1$.

Step 1: Perform an SVD $A_{21} = U_{21} \begin{bmatrix} \Sigma_{21} & 0 \\ 0 & 0 \end{bmatrix} V_{21}^T$ with nonsingular and diagonal $\Sigma_{21} \in \mathbb{R}^{n_2, n_2}$. Set

$$P_2 := \begin{bmatrix} V_{21}^T & 0 \\ 0 & U_{21}^T \end{bmatrix}, \quad P := P_2 P$$

so that

$$A := P_2 A P_2^T =: \begin{bmatrix} A_{11} & A_{12} & A_{13} \\ A_{21} & A_{22} & A_{23} \\ 0 & A_{32} & A_{33} \end{bmatrix},$$

$$B := P_2 B =: \begin{bmatrix} B_1 & 0 \\ 0 & 0 \\ 0 & 0 \end{bmatrix},$$

where $A_{21} = [\Sigma_{21} \ 0]$, and $B_1 := V_{21}^T \Sigma_B$.

Step 2:

$i = 3$

DO WHILE ($n_{i-1} > 0$ AND $A_{i,i-1} \neq 0$).

 Perform an SVD of $A_{i,i-1} = U_{i,i-1}$

$$\begin{bmatrix} \Sigma_{i,i-1} & 0 \\ 0 & 0 \end{bmatrix} V_{i,i-1}^T \text{ with}$$

$\Sigma_{i,i-1} \in \mathbb{R}^{n_i, n_i}$ nonsingular and diagonal.

Set

$$P_i := \begin{bmatrix} I_{n_1} & & & \\ & \ddots & & \\ & & I_{n_{i-2}} & \\ & & & V_{i,i-1}^T \\ & & & & U_{i,i-1}^T \end{bmatrix}, P := P_i P,$$

so that

$$A := P_i A P_i^T =: \begin{bmatrix} A_{11} & \cdots & A_{1,i+1} \\ A_{21} & \ddots & A_{2,i+1} \\ & \ddots & \vdots \\ & & A_{i,i-1} & A_{i,i} & \vdots \\ 0 & & A_{i+1,i} & A_{i+1,i+1} \end{bmatrix}$$

where $A_{i,i-1} = [\Sigma_{i,i-1} \ 0]$.

$i := i + 1$

END

$r := i$

It is clear that this algorithm will stop with $n_i = 0$ or $A_{i,i-1} = 0$. In every step, the remaining block shrinks at least by 1 row/column, as long as $\text{Rank } A_{i,i-1} > 1$, so that the algorithm stops after maximally $n - 1$ steps. It has been shown in Van Dooren (1981) that system (1) is controllable if and only if in the staircase form of (A, B) one has $n_r = 0$.

It should be noted that the updating transformations P_i of this algorithm will affect previously created “stairs” so that the blocks denoted as $\Sigma_{i,i-1}$ will not be diagonal anymore, but their singular values are unchanged. This is critical in the decision about the controllability of the pair (A, B) since it depends on the numerical rank of the submatrices $A_{i,i-1}$ and B (see Demmel and Kågström 1993). Based on this and a detailed error and perturbation analysis, the Staircase Algorithm has been implemented in the SLICOT routine AB01OD, and it uses in the worst-case $\mathcal{O}(n^4)$ flops (a “flop” is an elementary floating-point operation $+$, $-$, $*$, or $/$). For efficiency reasons, the SLICOT routine AB01OD does not use SVDs for rank decisions, but QR decompositions with column pivoting. When applying the corresponding orthogonal transformations to the system without accumulating them, the complexity can be reduced to $\mathcal{O}(n^3)$ flops. It has been provided with error bounds, condition estimates, and warning strategies.

Summary and Future Directions

We have presented the SLICOT library and the basic principles for the design of such basic subroutine libraries. To illustrate these principles, we have presented the development of a method for checking controllability for a linear time-invariant control system. But the SLICOT library contains much more than that. It essentially covers most of the problems listed in the selected reprint volume (Patel et al. 1994). This volume contained in 1994 the state of the art in numerical methods for systems and control, but the field has strongly evolved since then. Examples of areas that were not in this volume but that are included in SLICOT are periodic systems, differential algebraic equations, and model reduction. Areas which still need new results and software are the control of large-scale systems, obtained either from discretizations of partial differential equations or from the interconnection of a large number of interacting systems. But it is unclear for the moment which will be the

methods of choice for such problems. We still need to understand the numerical challenges in such areas, before we can propose numerically reliable software for these problems: the area is still quite open for new developments.

Bilinear Control of Schrödinger PDEs

Karine Beauchard¹ and Pierre Rouchon²

¹CNRS, CMLS, Ecole Polytechnique, Palaiseau, France

²Centre Automatique et Systèmes, Mines ParisTech, Paris Cedex 06, France

Abstract

This entry is an introduction to modern issues about controllability of Schrödinger PDEs with bilinear controls. This model is pertinent for a quantum particle, controlled by an electric field. We review recent developments in the field, with discrimination between exact and approximate controllabilities, in finite or

infinite time. We also underline the variety of mathematical tools used by various teams in the last decade. The results are illustrated on several classical examples.

Keywords

Approximate controllability · Global exact controllability · Local exact controllability · Quantum particles · Schrödinger equation · Small-time controllability

Introduction

A quantum particle, in a space with dimension N ($N = 1, 2, 3$), in a potential $V = V(x)$, and in an electric field $u = u(t)$, is represented by a wave function $\psi : (t, x) \in \mathbb{R} \times \Omega \rightarrow \mathbb{C}$ on the $L^2(\Omega, \mathbb{C})$ sphere S

$$\int_{\Omega} |\psi(t, x)|^2 dx = 1, \quad \forall t \in \mathbb{R},$$

where $\Omega \subset \mathbb{R}^N$ is a possibly unbounded open domain. In first approximation, the time evolution of the wave function is given by the Schrödinger equation,

$$\begin{cases} i \partial_t \psi(t, x) = (-\Delta + V) \psi(t, x) \\ -u(t) \mu(x) \psi(t, x), \quad t \in (0, +\infty), x \in \Omega, \\ \psi(t, x) = 0, \quad x \in \partial\Omega \end{cases} \quad (1)$$

where μ is the dipolar moment of the particle and $\hbar = 1$ here. Sometimes, this equation is considered in the more abstract framework

$$i \frac{d}{dt} \psi = (H_0 + u(t)H_1) \psi \quad (2)$$

where ψ lives on the unit sphere of a separable Hilbert space $\mathcal{H}$ and the Hamiltonians H_0, H_1 are Hermitian operators on $\mathcal{H}$. A natural question, with many practical applications, is the existence of a control u that steers the wave function ψ from a given initial state ψ_0 , to a prescribed target ψ_f .

The goal of this survey is to present well-established results concerning exact and approximate controllabilities for the bilinear control system (1), with applications to relevant

examples. The main difficulties are the infinite dimension of $\mathcal{H}$ and the nonlinearity of the control system.

Preliminary Results

When the Hilbert space $\mathcal{H}$ has finite dimension n , then controllability of Eq. (2) is well understood (D'Alessandro 2008). If, for example, the Lie algebra spanned by H_0 and H_1 coincides with $u(n)$, the set of skew-Hermitian matrices, then system (2) is globally controllable: for any initial and final states $\psi_0, \psi_f \in \mathcal{H}$ of length one, there exist $T > 0$ and a bounded open-loop control $[0, T] \ni t \mapsto u(t)$ steering ψ from $\psi(0) = \psi_0$ to $\psi(T) = \psi_f$.

In infinite dimension, this idea served to intuit a negative controllability result in Mirrahimi and Rouchon (2004), but the above characterization cannot be generalized because iterated Lie brackets of unbounded operators are not necessarily well defined. For example, the quantum harmonic oscillator

$$\begin{aligned} i \partial_t \psi(t, x) = & -\partial_x^2 \psi(t, x) + x^2 \psi(t, x) \\ & - u(t) x \psi(t, x), \quad x \in \mathbb{R}, \end{aligned} \quad (3)$$

is not controllable (in any reasonable sense) (Mirrahimi and Rouchon 2004) even if all its Galerkin approximations are controllable (Fu et al. 2001). Thus, much care is required in the use of Galerkin approximations to prove controllability in infinite dimension. This motivates the search of different methods to study exact controllability of bilinear PDEs of form (1).

In infinite dimension, the norms need to be specified. In this article, we use Sobolev norms. For $s \in \mathbb{N}$, the Sobolev space $H^s(\Omega)$ is the space of functions $\psi: \Omega \rightarrow \mathbb{C}$ with square integrable derivatives $d^k \psi$ for $k = 0, \dots, s$ (derivatives are well defined in the distribution sense). $H^s(\Omega)$ is endowed with the norm $\|\psi\|_{H^s} := \left(\sum_{k=0}^s \|d^k \psi\|_{L^2(\Omega)}^2 \right)^{1/2}$. We also use the space $H_0^1(\Omega)$ which contains functions $\psi \in H^1(\Omega)$ that

vanish on the boundary $\partial\Omega$ (in the trace sense) (Brézis 1999).

The first control result of the literature states the noncontrollability of system (1) in $(H^2 \cap H_0^1)(\Omega) \cap S$ with controls $u \in L^2((0, T), \mathbb{R})$ (Turinici 2000; Ball et al. 1982). More precisely, by applying $L^2(0, T)$ controls u , the reachable wave functions $\psi(T)$ form a subset of $(H^2 \cap H_0^1)(\Omega) \cap S$ with empty interior. This statement does not give obstructions for system (1) to be controllable in different functional spaces as we will see below, but it indicates that controllability issues are much more subtle in infinite dimension than in finite dimension.

Local Exact Controllability

In 1D and with Discrete Spectrum

This section is devoted to the 1D PDE:

$$\begin{cases} i \partial_t \psi(t, x) = -\partial_x^2 \psi(t, x) \\ -u(t) \mu(x) \psi(t, x), \quad x \in (0, 1), t \in (0, T), \\ \psi(t, 0) = \psi(t, 1) = 0. \end{cases} \quad (4)$$

We call “ground state” the solution of the free system ($u = 0$) built with the first eigenvalue and eigenvector of $-\partial_x^2$: $\psi_1(t, x) = \sqrt{2} \sin(\pi x) e^{-i\pi^2 t}$. Under appropriate assumptions on the dipolar moment μ , then system (4) is controllable around the ground state, locally in $H_0^3(0, 1) \cap S$, with controls in $L^2((0, T), \mathbb{R})$, as stated below.

Theorem 1 Assume $\mu \in H^3((0, 1), \mathbb{R})$ and

$$\left| \int_0^1 \mu(x) \sin(\pi x) \sin(k\pi x) dx \right| \geq \frac{c}{k^3}, \quad \forall k \in \mathbb{N}^* \quad (5)$$

for some constant $c > 0$. Then, for every $T > 0$, there exists $\delta > 0$ such that for every $\psi_0, \psi_f \in S \cap H_0^3((0, 1), \mathbb{C})$ with $\|\psi_0 - \psi_1(0)\|_{H^3} + \|\psi_f - \psi_1(T)\|_{H^3} < \delta$, there exists $u \in L^2((0, T), \mathbb{R})$ such that the solution of (4) with initial condition $\psi(0, x) = \psi_0(x)$ satisfies $\psi(T) = \psi_f$.

Here, $H_0^3(0, 1) := \{\psi \in H^3((0, 1), \mathbb{C}); \psi = \psi'' = 0 \text{ at } x = 0, 1\}$. We refer to Beauchard and Laurent (2010) and Beauchard et al. (2013) for proof and generalizations to nonlinear PDEs. The proof relies on the linearization principle, by applying the classical inverse mapping theorem to the endpoint map. Controllability of the linearized system around the ground state is a consequence of assumption (5) and classical results about trigonometric moment problems. A subtle smoothing effect allows to prove C^1 regularity of the endpoint map.

The assumption (5) holds for generic $\mu \in H^3((0, 1), \mathbb{R})$ and plays a key role for local exact controllability to hold in *small* time T . In Beauchard and Morancey (2014), local exact controllability is proved under the weaker assumption, namely, $\mu'(0) \pm \mu'(1) \neq 0$, but only in *large* time T .

Moreover, under appropriate assumptions on μ , references Coron (2006) and Beauchard and Morancey (2014) propose explicit motions that are impossible in small time T , with small controls in L^2 . Thus, a positive minimal time is required for local exact controllability, even if information propagates at infinite speed. This minimal time is due to nonlinearities; its characterization is an open problem.

Actually, assumption $\mu'(0) \pm \mu'(1) \neq 0$ is not necessary for local exact controllability in large time. For instance, the quantum box, i.e.,

$$\begin{cases} i \partial_t \psi(t, x) = -\partial_x^2 \psi(t, x) \\ -u(t)x \psi(t, x), \quad x \in (0, 1), \\ \psi(t, 0) = \psi(t, 1) = 0, \end{cases} \quad (6)$$

is treated in Beauchard (2005). Of course, these results are proved with additional techniques: power series expansions and Coron’s return method (Coron 2007).

There is no contradiction between the negative result of section “Preliminary Results” and the positive result of Theorem 1. Indeed, the wave function cannot be steered between any two points ψ_0, ψ_f of $H^2 \cap H_0^1$, but it can be steered between any two points ψ_0, ψ_f of

$H_{(0)}^3$, which is smaller than $H^2 \cap H_0^1$. In particular, $H_{(0)}^3((0, 1), \mathbb{C})$ has an empty interior in $H_{(0)}^2((0, 1), \mathbb{C})$. Thus, there is no incompatibility between the reachable set to have empty interior in $H^2 \cap H_0^1$ and the reachable set to coincide with $H_{(0)}^3$.

Open Problems in Multi-D or with Continuous Spectrum

The linearization principle used to prove Theorem 1 does not work in multi-D: the trigonometric moment problem, associated to the controllability of the linearized system, cannot be solved. Indeed, its frequencies, which are the eigenvalues of the Dirichlet Laplacian operator, do not satisfy a required gap condition (Loreti and Komornik 2005).

The study of a toy model (Beauchard 2011) suggests that if local controllability holds in 2D (with a priori bounded L^2 -controls) then a positive minimal time is required, whatever μ is. The appropriate functional frame for such a result is an open problem.

In 3D or in the presence of continuous spectrum, we conjecture that local exact controllability does not hold (with a priori bounded L^2 -controls) because the gap condition in the spectrum of the Dirichlet Laplacian operator is violated (see Beauchard et al. (2010) for a toy model from nuclear magnetic resonance and ensemble controllability as originally stated in Li and Khaneja (2009)). Thus, exact controllability should be investigated with controls that are not a priori bounded in L^2 ; this requires new techniques. We refer to Nersesyan and Nersisyan (2012a) for precise negative results.

Finally, we emphasize that exact controllability in multi-D but in *infinite* time has been proved in Nersesyan and Nersisyan (2012a, b), with techniques similar to one used in the proof of Theorem 1.

Approximate Controllability

Different approaches have been developed to prove approximate controllability.

Lyapunov Techniques

Due to measurement effect and back action, closed-loop controls in the Schrödinger frame are not appropriate. However, closed-loop controls may be computed via numerical simulations and then applied to real quantum systems in open loop, without measurement. Then, the strategy consists in designing damping feedback laws, thanks to a controlled Lyapunov function, which encodes the distance to the target. In finite dimension, the convergence proof relies on LaSalle invariance principle. In infinite dimension, this principle works when the trajectories of the closed-loop system are compact (in the appropriate space), which is often difficult to prove. Thus, two adaptations have been proposed: approximate convergence (Beauchard and Mirrahimi 2009; Mirrahimi 2009) and weak convergence (Beauchard and Nersesyan 2010) to the target.

Variational Methods and Global Exact Controllability

The global approximate controllability of (1), in any Sobolev space, is proved in Nersesyan (2010), under generic assumptions on (V, μ) , with Lyapunov techniques and variational arguments.

Theorem 2 *Let $V, \mu \in C^\infty(\bar{\Omega}, \mathbb{R})$ and $(\lambda_j)_{j \in \mathbb{N}^*}, (\phi_j)_{j \in \mathbb{N}^*}$ be the eigenvalues and normalized eigenvectors of $(-\Delta + V)$. Assume $\langle \mu \phi_j, \phi_1 \rangle \neq 0$, for all $j \geq 2$ and $\lambda_1 - \lambda_j \neq \lambda_p - \lambda_q$ for all $j, p, q \in \mathbb{N}^*$ such that $\{1, j\} \neq \{p, q\}; j \neq 1$. Then, for every $s > 0$, the system (1) is globally approximately controllable in $H_{(V)}^s : D[(-\Delta + V)^{s/2}]$, the domain of $(-\Delta + V)^{s/2}$: for every $\epsilon, \delta > 0$ and $\psi_0 \in S \cap H_{(V)}^s$, there exist a time $T > 0$ and a control $u \in C_0^\infty((0, T), \mathbb{R})$ such that the solution of (1) with initial condition $\psi(0) = \psi_0$ satisfies $\|\psi(T) - \phi_1\|_{H_{(V)}^{s-\delta}} < \epsilon$.*

This theorem is of particular importance. Indeed, in 1D and for appropriate choices of (V, μ) , global exact controllability of (1) in H^{3+} can be proved by combining the following:

- Global approximate controllability in H^3 given by Theorem 2,
- Local exact controllability in H^3 given by Theorem 1,
- Time reversibility of the Schrödinger equation (i.e., if $(\psi(t, x), u(t))$ is a trajectory, then so is $(\psi^*(T - t, x), u(T - t))$ where ψ^* is the complex conjugate of ψ).

Let us expose this strategy on the quantum box (6). First, one can check the assumptions of Theorem 2 with $V(x) = \gamma x$ and $\mu(x) = (1 - \gamma)x$ when $\gamma > 0$ is small enough. This means that, in (6), we consider controls $u(t)$ of the form $\gamma + u(t)$. Thus, an initial condition $\psi_0 \in H_{(0)}^{3+}$ can be steered arbitrarily close to the first eigenvector $\phi_{1,\gamma}$ of $(-\partial_x^2 + \gamma x)$, in H^3 norm. Moreover, by a variant of Theorem 1, the local exact controllability of (6) holds in $H_{(0)}^3$ around $\phi_{1,\gamma}$. Therefore, the initial condition $\psi_0 \in H_{(0)}^{3+}$ can be steered exactly to $\phi_{1,\gamma}$ in finite time. By the time reversibility of the Schrödinger equation, we can also steer exactly the solution from $\phi_{1,\gamma}$ to any target $\psi_f \in H^{3+}$. Therefore, the solution can be steered exactly from any initial condition $\psi_0 \in H_{(0)}^{3+}$ to any target $\psi_f \in H_{(0)}^{3+}$ in finite time.

Geometric Techniques Applied to Galerkin Approximations

In Boscain et al. (2012, 2013) and Chambrion et al. (2009) the authors study the control of Schrödinger PDEs, in the abstract form (2) and under technical assumptions on the (unbounded) operators H_0 and H_1 that ensure the existence of solutions with piecewise constant controls u :

1. H_0 is skew-adjoint on its domain $D(H_0)$.
2. There exists a Hilbert basis $(\phi_k)_{k \in \mathbb{N}}$ of $\mathcal{H}$ made of eigenvectors of $H_0 : H_0 \phi_k = i\lambda_k \phi_k$ and $\phi_k \in D(H_1), \forall k \in \mathbb{N}$.
3. $H_0 + uH_1$ is essentially skew-adjoint (not necessarily with domain $D(H_0)$) for every $u \in [0, \delta]$ for some $\delta > 0$.

4. $\langle H_1 \phi_j, \phi_k \rangle = 0$ for every $j, k \in \mathbb{N}$ such that $\lambda_j = \lambda_k$ and $j \neq k$.

Theorem 3 Assume that, for every $j, k \in \mathbb{N}$, there exists a finite number of integers $p_1, \dots, p_r \in \mathbb{N}$ such that

$$p_1 = j, \quad p_r = k, \quad \langle H_1 \phi_{p_l}, \phi_{p_{l+1}} \rangle \neq 0, \quad \forall l = 1, \dots, r-1$$

$|\lambda_L - \lambda_M| \neq |\lambda_{p_l} - \lambda_{p_{l+1}}|, \forall 1 \leq l \leq r-1, LM \in \mathbb{N}$ with $\{L, M\} \neq \{p_l, p_{l+1}\}$.

Then for every $\epsilon > 0$ and ψ_0, ψ_f in the unit sphere of $\mathcal{H}$, there exists a piecewise constant function $u : [0, T_\epsilon] \rightarrow [0, \delta]$ such that the solution of (2) with initial condition $\psi(0) = \psi_0$ satisfies $\|\psi(T_\epsilon) - \psi_f\|_{\mathcal{H}} < \epsilon$.

We refer to Boscain et al. (2012, 2013) and Chambrion et al. (2009) for proof and additional results such as estimates on the L^1 norm of the control. Note that H_0 is not necessarily of the form $(-\Delta + V)$, H_1 can be unbounded, δ may be arbitrary small, and the two assumptions are generic with respect to (H_0, H_1) . The connectivity and transition frequency conditions in Theorem 3 mean physically that each pair of H_0 eigenstates is connected via a finite number of first-order (one-photon) transitions and that the transition frequencies between pairs of eigenstates are all different.

Note that, contrary to Theorems 2, Theorem 3 cannot be combined with Theorem 1 to prove global exact controllability. Indeed, functional spaces are different: $\mathcal{H} = L^2(\Omega)$ in Theorem 3, whereas H^3 -regularity is required for Theorem 1.

This kind of results applies to several relevant examples such as the control of a particule in a quantum box by an electric field (6) and the control of the planar rotation of a linear molecule by means of two electric fields:

$$i \partial_t \psi(t, \theta) = \left(-\partial_\theta^2 + u_1(t) \cos(\theta) + u_2(t) \sin(\theta) \right) \psi(t, \theta), \quad \theta \in \mathbb{T}$$

where $\mathbb{T}$ is the 1D-torus. However, several other systems of physical interest are not covered by these results such as trapped ions modeled by two coupled quantum harmonic oscillators. In Ervedoza and Puel (2009), specific methods have been used to prove their approximate controllability.

Concluding Remarks

The variety of methods developed by different authors to characterize controllability of Schrödinger PDEs with bilinear control is the sign of a rich structure and subtle nature of control issues. New methods will probably be necessary to answer the remaining open problems in the field.

This survey is far from being complete. In particular, we do not consider numerical methods to derive the steering control such as those used in NMR (Nielsen et al. 2010) to achieve robustness versus parameter uncertainties or such as monotone algorithms (Baudouin and Salomon 2008; Liao et al. 2011) for optimal control (Cancès et al. 2000). We do not consider also open quantum systems where the state is then the density operator ρ , a nonnegative Hermitian operator with unit trace on $\mathcal{H}$. The Schrödinger equation is then replaced by the Lindblad equation:

$$\begin{aligned} \frac{d}{dt}\rho = & -i[H_0 + uH_1, \rho] + \sum_v L_v \rho L_v^\dagger \\ & - \frac{1}{2} \left(L_v^\dagger L_v \rho + \rho L_v^\dagger L_v \right) \end{aligned}$$

with operator L_v related to the decoherence channel v . Even in the case of finite dimensional Hilbert space $\mathcal{H}$, controllability of such system is not yet well understood and characterized (see Altafini (2003) and Kurniawan et al. (2012)).

Boundary Control of 1-D Hyperbolic Systems

Georges Bastin¹ and Jean-Michel Coron²

¹Department of Mathematical Engineering, ICTEAM, UCLouvain, Louvain-La-Neuve, Belgium

²Laboratoire Jacques-Louis Lions, Sorbonne Université, Paris, France

Abstract

One-dimensional hyperbolic systems are commonly used to describe the evolution of various physical systems. For many of these systems, controls are available on the boundary. There are then two natural questions: controllability (steer the system from a given state to a desired target) and stabilization (construct feedback laws leading to a good behavior of the closed-loop system around a given set point).

Keywords

Hyperbolic systems · Controllability · Stabilization · Electrical lines · Open channels · Road traffic · Chromatography

One-Dimensional Hyperbolic Systems

The operation of many physical systems may be represented by hyperbolic systems in one space dimension. These systems are described by the following partial differential equation:

$$\begin{aligned} Y_t + F(Y)Y_x + G(Y) &= 0, \\ t \in [0, T], \quad x \in [0, L], \end{aligned} \quad (1)$$

where

- t and x are two independent variables: a time variable $t \in [0, T]$ and a space variable $x \in [0, L]$ over a finite interval;

- $Y : [0, T] \times [0, L] \rightarrow \mathbb{R}^n$ is the vector of state variables;
- $F : \mathbb{R}^n \rightarrow \mathcal{M}_{n,n}(\mathbb{R})$ where $\mathcal{M}_{n,n}(\mathbb{R})$ denotes the set of $n \times n$ real matrices;
- $G : \mathbb{R}^n \rightarrow \mathbb{R}^n$;
- Y_t and Y_x denote the partial derivatives of Y with respect to t and x , respectively.

The system (1) is **hyperbolic** which means that $F(Y)$ has n distinct real eigenvalues (called characteristic velocities) for all Y in a domain $\mathcal{Y}$ of $\mathbb{R}^n$. It is furthermore assumed that these eigenvalues never vanish and therefore do not change sign along the system trajectories in $\mathcal{Y}$.

Here are some typical examples of physical models having the form of a hyperbolic system.

Electrical Lines

First proposed by Heaviside in 1885, the equations of (lossless) electrical lines (also called telegrapher equations) describe the propagation of current and voltage along electrical transmission lines (see Fig. 1). It is a hyperbolic system of the following form:

$$\begin{pmatrix} I_t \\ V_t \end{pmatrix} + \begin{pmatrix} 0 & L_s^{-1} \\ C_s^{-1} & 0 \end{pmatrix} \begin{pmatrix} I_x \\ V_x \end{pmatrix} + \begin{pmatrix} R_s L_s^{-1} I \\ G_s C_s^{-1} V \end{pmatrix} = 0, \quad (2)$$

where $I(t, x)$ is the current intensity, $V(t, x)$ is the voltage, L_s is the line self-inductance per unit of length, C_s is the line self-capacitance per unit of length, R_s is the resistance of the two conductors per unit of length, and G_s is the admittance per unit of length of the dielectric material separating the conductors. The system has two characteristic velocities (which are the two distinct non-zero eigenvalues of the matrix F):

$$\lambda_1 = \frac{1}{\sqrt{L_s C_s}} > 0 > \lambda_2 = -\frac{1}{\sqrt{L_s C_s}}. \quad (3)$$

Saint-Venant Equation for Open Channels

First proposed by Barré-de-Saint-Venant in 1871, the Saint-Venant equations (also called *shallow water equations*) describe the propagation of water in open channels (see Fig. 2). In the case of a horizontal channel with rectangular cross section, unit width, and friction, the Saint-Venant model is a hyperbolic system of the form

$$\begin{pmatrix} H_t \\ V_t \end{pmatrix} + \begin{pmatrix} V & H \\ g & V \end{pmatrix} \begin{pmatrix} H_x \\ V_x \end{pmatrix} + \begin{pmatrix} 0 \\ c_f V^2/H \end{pmatrix} = 0, \quad (4)$$

where $H(t, x)$ is the water depth, $V(t, x)$ is the water horizontal velocity, g is the gravity acceleration, and c_f is a friction coefficient. Under sub-

Boundary Control of 1-D Hyperbolic Systems, Fig. 1 Transmission line connecting a power supply to a resistive load R_ℓ ; the power supply is represented by a Thevenin equivalent with $efm U(t)$ and internal resistance R_g

Boundary Control of 1-D Hyperbolic Systems,

Fig. 2 Lateral view of a pool of a horizontal open channel

critical flow conditions, the system is hyperbolic with characteristic velocities

$$\lambda_1 = V + \sqrt{gH} > 0 > \lambda_2 = V - \sqrt{gH}. \quad (5)$$

Aw-Rascle Equations for Fluid Models of Road Traffic

In the fluid paradigm for road traffic modeling, the traffic is described in terms of two basic macroscopic state variables: the density $\varrho(t, x)$ and the speed $V(t, x)$ of the vehicles at position x along the road at time t . The following dynamical model for road traffic was proposed by Aw and Rascle in (2000):

$$\begin{aligned} \begin{pmatrix} \varrho_t \\ V_t \end{pmatrix} + \begin{pmatrix} V & \varrho \\ 0 & V - \varrho P'(\varrho) \end{pmatrix} \begin{pmatrix} \varrho_t \\ V_t \end{pmatrix} \\ + \begin{pmatrix} 0 \\ \sigma(V - V_o(\varrho)) \end{pmatrix} = 0. \end{aligned} \quad (6)$$

The system is hyperbolic with characteristic velocities

$$\lambda_1 = V > \lambda_2 = V - \varrho P'(\varrho). \quad (7)$$

In this model the first equation is a continuity equation that represents the conservation of the number of vehicles on the road. The second equation is a phenomenological model describing the speed variations induced by the drivers behavior. The function $P(\varrho)$ is a monotonically increasing function called *traffic pressure*. The function $V_o(\rho)$ represents the monotonically decreasing relation between the average speed of the vehicles and the traffic density. The parameter σ is a relaxation constant.

Chromatography

In chromatography, a mixture of species with different affinities is injected in the carrying fluid at the entrance of the process as illustrated in Fig. 3. Various substances travel at different propagation speeds and are ultimately separated in different bands. The dynamics of the mixture are described by a system of partial differential equations:

Boundary Control of 1-D Hyperbolic Systems, Fig. 3
Principle of chromatography

$$(P_i + L_i(P))_t + (V P_i)_x = 0 \quad i = 1, \dots, n,$$

$$L_i(P) = \frac{k_i P_i}{1 + \sum_j k_j P_j / P_{\max}}, \quad (8)$$

where V denotes the speed of the carrying fluid while P_i ($i = 1, \dots, n$) denote the densities of the n carried species. The function $L_i(P)$ (called the “Langmuir isotherm”) was proposed by Langmuir in 1916.

Boundary Control

Boundary control of 1-D hyperbolic systems refers to situations where manipulable control inputs are physically located at the boundaries. Formally, this means that the system (1) is considered under n boundary conditions having the general form

$$\mathcal{B}(Y(t, 0), Y(t, L), U(t)) = 0, \quad (9)$$

with $\mathcal{B} : \mathbb{R}^n \times \mathbb{R}^n \times \mathbb{R}^q \rightarrow \mathbb{R}^n$. The dependence of the map $\mathcal{B}$ on $(Y(t, 0), Y(t, L))$ refers to natural physical constraints on the system. The function $U(t) \in \mathbb{R}^q$ represents a set of q exogenous control inputs. The following examples illustrate how the control boundary conditions (9) may be defined for some commonly used control devices.

1. **Electrical lines.** For the circuit represented in Fig. 1, the line model (2) is to be considered under the following boundary conditions:

$$V(t, 0) + R_g I(t, 0) = U(t),$$

$$V(t, L) - R_\ell I(t, L) = 0.$$

The telegrapher equations (2) coupled with these boundary conditions constitute therefore a boundary control system with the voltage $U(t)$ as control input.

2. **Open channels.** A standard situation is when the boundary conditions are assigned by tunable hydraulic gates as in irrigation canals and navigable rivers; see Fig. 4. The hydraulic

model of overshoot gates gives the boundary conditions

$$H(t, 0)V(t, 0) = k_G \sqrt{[Z_0(t) - U_0(t)]^3},$$

$$H(t, L)V(t, L) = k_G \sqrt{[H(t, L) - U_L(t)]^3}.$$

In these equations $H(t, 0)$ and $H(t, L)$ denote the water depth at the boundaries inside the pool, $Z_0(t)$ and $Z_L(t)$ are the water levels on the other side of the gates, k_G is a constant gate shape parameter, and U_0 and U_L represent the weir elevations. The Saint-Venant equations coupled to these boundary conditions constitute a boundary control system with $U_0(t)$ and $U_L(t)$ as command signals.

3. **Ramp metering.** Ramp metering is a strategy that uses traffic lights to regulate the flow of traffic entering freeways according to measured traffic conditions as illustrated in Fig. 5. For the stretch of motorway represented in this figure, the boundary conditions are

$$q(t, 0)V(t, 0) = Q_{in}(t) + U(t),$$

$$q(t, L)V(t, L) = Q_{out}(t),$$

Boundary Control of 1-D Hyperbolic Systems,

Fig. 4 Hydraulic overshoot gates at the input and the output of a pool

Boundary Control of 1-D Hyperbolic Systems,

Fig. 5 Ramp metering on a stretch of a motorway

where $U(t)$ is the inflow rate controlled by the traffic lights. The Aw-Rascle equations (6) coupled to these boundary conditions constitute a boundary control system with $U(t)$ as the command signal. In a feedback implementation of the ramp metering strategy, $U(t)$ may be a function of the measured disturbances $Q_{\text{int}}(t)$ or $Q_{\text{out}}(t)$ that are imposed by the traffic conditions.

4. **Simulated moving bed chromatography** is a technology where several interconnected chromatographic columns are switched periodically against the fluid flow. This allows for a continuous separation with a better performance than the discontinuous single-column chromatography. An efficient operation of SMB chromatography requires a tight control of the process by manipulating the inflow rates in the columns. This process

is therefore a typical example of a periodic boundary control hyperbolic system.

Steady State and Change of Coordinates

A steady state (or equilibrium) of the system (1)–(9) is a time-invariant solution $Y(t, x) = Y^*(x)$, $U(t) = U^*$, $\forall t \in [0, +\infty)$. It satisfies the ordinary differential equation

$$F(Y^*)Y_x^* + G(Y^*) = 0, \quad x \in [0, L], \quad (10)$$

together with the boundary condition

$$\mathcal{B}(Y^*(0), Y^*(L), U^*) = 0. \quad (11)$$

Having distinct eigenvalues by assumption, the matrix $F(Y^*(x))$ is diagonalizable:

$$\begin{aligned} \exists N(x) \in \mathcal{M}_{n,n}(\mathbb{R}) \quad \text{such that} \quad N(x)F(Y^*(x)) &= \Lambda(x)N(x), \\ \text{with} \quad \Lambda(x) &= \text{diag}\{\lambda_1(x), \dots, \lambda_n(x)\}, \end{aligned}$$

where $\lambda_i(x)$ is the i -th eigenvalue of the matrix $F(Y^*(x))$. Furthermore, it is assumed that for all x , there are m positive and $n - m$ negative eigenvalues as follows:

$$\begin{aligned} \lambda_i(x) &> 0 \quad \forall i \in \{1, 2, \dots, m\}, \\ \lambda_i(x) &< 0 \quad \forall i \in \{m+1, \dots, n\}, \end{aligned} \quad (12)$$

such that the matrix $\Lambda(x)$ is written

$$\Lambda(x) = \begin{pmatrix} \Lambda^+(x) & 0 \\ 0 & \Lambda^-(x) \end{pmatrix} \quad (13)$$

with $\Lambda^+ = \text{diag}\{\lambda_1, \lambda_2, \dots, \lambda_m\}$ and $\Lambda^- = \text{diag}\{\lambda_{m+1}, \lambda_{m+2}, \dots, \lambda_n\}$.

Then, with the change of coordinates

$$Z(t, x) = N(x)(Y(t, x) - Y^*(x)), \quad (14)$$

the control system (1)–(9) is equivalent to the system

$$Z_t + A(Z, x)Z_x + B(Z, x)Z = 0, \quad (15)$$

$$\begin{aligned} \mathcal{B}(N(0)^{-1}Z(t, 0) + Y^*(0), \\ N(L)^{-1}Z(t, L) + Y^*(L), U(t)) &= 0, \end{aligned} \quad (16)$$

where

$$A(Z, x) = N(x)F(N(x)^{-1}Z + Y^*(x))N(x)^{-1} \text{ with } A(0, x) = \Lambda(x), \quad (17)$$

$$\begin{aligned} B(Z, x)Z &= N(x) \left[F(N^{-1}(x)Z + Y^*(x))(Y_x^*(x) \right. \\ &\quad \left. - N(x)^{-1}N'(x)N(x)^{-1}Z) + G(N(x)^{-1}Z + Y^*(x)) \right]. \end{aligned} \quad (18)$$

Controllability

For the boundary control system (1)–(9), the local controllability issue is to investigate if, starting from a given initial state $Y_0 : x \in [0, L] \mapsto Y_0(x) \in \mathbb{R}^n$, it is possible to reach in time T a desired target state $Y_1 : x \in [0, L] \mapsto Y_1(x) \in \mathbb{R}^n$, with $Y_0(x)$ and $Y_1(x)$ close to $Y^*(x)$. Using the state transformation of the previous section, this controllability problem for the physical system (1)–(9) is equivalent to, starting from a given initial state $Z_0 : x \in [0, L] \mapsto Z_0(x) \in \mathbb{R}^n$, to reach in time T a desired target state $Z_1 : x \in$

$[0, L] \mapsto Z_1(x) \in \mathbb{R}^n$, with $Z_0(x)$ and $Z_1(x)$ close to 0, for the auxiliary system (15)–(16).

Let $Z^+ \in \mathbb{R}^m$ and $Z^- \in \mathbb{R}^{n-m}$ be such that $Z^T = (Z^{+T} \ Z^{-T})^T$.

Theorem 1 *If there exist control inputs $U^+(t)$ and $U^-(t)$ such that the boundary conditions (16) are equivalent to*

$$Z^+(t, 0) = U^+(t), \quad Z^-(t, L) = U^-(t), \quad (19)$$

then the boundary control system (15) and (16) is locally controllable for the C^1 -norm if $T > T_c$ with

$$T_c = \max \left\{ \frac{L}{\min \{|\lambda_1(x)|; x \in [0, L]\}}, \dots, \frac{L}{\min \{|\lambda_n(x)|; x \in [0, L]\}} \right\}.$$

The proof of this theorem can be found in Wang (2006). For the special case where Y^* is constant, see also Li and Rao (2003).

Feedback Stabilization

For the boundary control system (1)–(9), the problem of local boundary feedback stabilization is the problem of finding a boundary feedback $U(Y(t, 0), Y(t, L))$ such that the system trajectory exponentially converges to a desired steady-state $Y^*(x)$ from any initial condition $Y_0(x)$ close to $Y^*(x)$. In such case, the steady state is said to be exponentially stabilizable.

From the system transformation of section “Steady State and Change of Coordinates”, it is clear that looking for a boundary stabilizing feedback $U(Y(t, 0), Y(t, L))$ for the physical

system (1)–(9) is equivalent to looking for a feedback $U(Z(t, 0), Z(t, L))$ that exponentially stabilizes the zero steady state of the auxiliary system (15)–(16).

Theorem 2 *Assume that there exists a boundary feedback $U(Z(t, 0), Z(t, L))$ such that the boundary condition (16) is written in the form*

$$\begin{pmatrix} Z^+(t, 0) \\ Z^-(t, L) \end{pmatrix} = \mathcal{H} \begin{pmatrix} Z^+(t, L) \\ Z^-(t, 0) \end{pmatrix}, \quad \mathcal{H}(0) = 0, \quad (20)$$

where $\mathcal{H} : \mathbb{R}^n \rightarrow \mathbb{R}^n$.

Then, for the boundary control system (15)–(16)–(20), the zero steady state is locally exponentially stable for the H^2 -norm if there exists a map $Q = \text{diag}\{Q^+, Q^-\}$ with $Q^+ : [0, L] \rightarrow \mathcal{D}^m$ and $Q^- : [0, L] \rightarrow \mathcal{D}^{n-m}$ such that the following matrix inequalities hold:

$$\begin{pmatrix} Q^+(L)\Lambda^+(L) & 0 \\ 0 & -Q^-(0)\Lambda^-(0) \end{pmatrix} - K^T \begin{pmatrix} Q^+(0)\Lambda^+(0) & 0 \\ 0 & -Q^-(L)\Lambda^-(L) \end{pmatrix} K > 0, \quad (21)$$

$$-(Q(x)\Lambda(x))_x + Q(x)B(0, x) + B^T(0, x)Q(x) > 0 \quad \forall x \in [0, L], \quad (22)$$

where $K = \mathcal{H}'(0)$ is the Jacobian matrix of the map $\mathcal{H}$ at 0 and $\mathcal{D}^k$ denotes the set of diagonal $k \times k$ matrices with positive diagonal entries.

The proof of this theorem can be found in Bastin and Coron (2016, Chapter 6). For the stabilization in the C^1 -norm, alternative sufficient conditions are given in Hayat (2017).

When the physical system is linear or when the steady state is uniform (i.e., Y^* is constant and independent of x), we have the interesting and important special case where the linearization of the control system (15)–(16)–(20) is written

$$Z_t + \Lambda Z_x + BZ = 0 \quad (23)$$

$$\begin{pmatrix} Z^+(t, 0) \\ Z^-(t, L) \end{pmatrix} = K \begin{pmatrix} Z^+(t, L) \\ Z^-(t, 0) \end{pmatrix}, \quad (24)$$

with Λ , B , and K constant matrices. In this special case, simpler and much more explicit stability conditions can be formulated as the one given in the next theorem.

Theorem 3 *If the feedback control $U(Z(t, 0), Z(t, L))$ can be selected such that the matrix $K = \mathcal{H}'(0)$ satisfies the inequality*

$$\inf \{ \|\Delta K \Delta^{-1}\|; \Delta \in \mathcal{D}^n \} < 1, \quad (25)$$

then there exists $\varepsilon > 0$, function of K , such that, if $\|B\| < \varepsilon$, the linear system (23) and (24) is exponentially stable for the L^2 -norm and the zero steady state of the nonlinear system (15)–(20) is locally exponentially stable for the H^2 -norm.

The proof of this theorem can be found in Bastin and Coron (2016, Chapters 3 and 6).

Future Directions

For further information on the controllability problem, in particular the case where there are controls on only one side of $[0, L]$, see Li (2010), Hu (2015), Coron and Nguyen (2019) and Hu and Olive (2019).

Concerning the stabilization problem, as shown in Bastin and Coron (2016, Section 5.6), there are cases where there are no feedback laws of the form (20) stabilizing Y^* . One needs to use nonlocal feedback laws. To construct such feedback laws, a possibility is to use the Krstic's backstepping approach Krstic and Smyshlyaev (2008): it was first done in Coron et al. (2013) for the case $n = 2$ and $m = 1$ and (Di Meglio et al. 2013; Auriol and Meglio 2016; Hu et al. 2016,

2019; Coron et al. 2017; Coron and Nguyen 2019) for more general cases.

In this note, we have only addressed the stabilization by proportional feedback of local measurable boundary states. In many practical situations, it is however well-known that there are load disturbances which cannot be measured and therefore not directly compensated in the control. In this case it is useful to implement integral actions in order to eliminate offsets and to attenuate the incidence of load disturbances. The stability of hyperbolic systems with proportional-integral (PI) control has been investigated, for instance, in Bastin and Coron (2016, Chapters 2, 5, and 8) and (Dos Santos et al. 2008; Bastin et al. 2015; Lamare and Bekiaris-Liberis 2015; Trinh et al. 2017; Coron and Hayat 2018; Hayat 2019). Another important issue for the system (1) is the observability problem: assume that the state is measured on the boundary during the interval of time $[0, T]$, can one recover the initial data? As shown in Li (2010), this problem has strong connections with the controllability problem, and the system (1) is observable if the time T is large enough.

The above results are on smooth solutions of (1). However, the system (1) is known to be well posed in class of BV -solutions (bounded variations), with extra conditions (e.g., entropy type); see in particular (Bressan 2000). There are partial results on the controllability in this class. See, in particular, (Ancona and Marson 1998; Horsin 1998) for $n = 1$. For $n = 2$, it is shown in Bressan and Coclite (2002) that Theorem 1 no longer holds in general the BV class. However there are positive results for important physical systems; see, for example, Glass (2007) for the 1-D isentropic Euler equation. Concerning the stabilization problem in the BV -class, see Coron et al. (2017).

Boundary Control of Korteweg-de Vries and Kuramoto-Sivashinsky PDEs

Eduardo Cerpa

Departamento de Matemática, Universidad
Técnica Federico Santa María, Valparaíso, Chile

Abstract

The Korteweg-de Vries (KdV) and the Kuramoto-Sivashinsky (KS) partial differential equations are used to model nonlinear propagation of one-dimensional phenomena. The KdV equation is used in fluid mechanics to describe wave propagation in shallow water surfaces, while the KS equation models front propagation in reaction-diffusion systems. In this article, the boundary control of these equations is considered when they are posed on a bounded interval. Different choices of controls are studied for each equation.

Dispersive equations · Parabolic equations

Introduction

The Korteweg-de Vries (KdV) and the Kuramoto-Sivashinsky (KS) equations have very different properties because they do not belong to the same class of partial differential equations (PDEs). The first one is a third-order nonlinear dispersive equation

$$y_t + y_x + y_{xxx} + yy_x = 0, \quad (1)$$

and the second one is a fourth-order nonlinear parabolic equation

$$u_t + u_{xxxx} + \lambda u_{xx} + uu_x = 0, \quad (2)$$

where $\lambda > 0$ is called the anti-diffusion parameter. However, they have one important characteristic in common. They are both used to model nonlinear propagation phenomena in the space x -direction when the variable t stands for time. The KdV equation serves as a model for wave propagation in shallow water surfaces (Korteweg and de Vries 1895), and the KS equation models front propagation in reaction-diffusion phenomena including some instability effects (Kuramoto and Tsuzuki 1975; Sivashinsky 1977).

From a control point of view, a new common characteristic arises. Because of the order of the spatial derivatives involved, when studying these equations on a bounded interval $[0, L]$, two boundary conditions have to be imposed at the same point, for instance, at $x = L$. Thus, we can consider control systems where we control one boundary condition but not all the boundary data at one endpoint of the interval. This configuration is not possible for the classical wave and heat equations where at each extreme, only one boundary condition exists and therefore controlling one or all the boundary data at one point is the same.

Being the KdV equation of third order in space, three boundary conditions have to be imposed: one at the left endpoint $x = 0$ and two at the right endpoint $x = L$. For the KS equation, four boundary conditions are needed to get a well-posed system, two at each extreme. We will focus on the cases where Dirichlet and Neumann boundary conditions are considered because lack of controllability phenomena appears. This holds for some special values of the length of the interval for the KdV equation and depends on the anti-diffusion coefficient λ for the KS equation.

The particular cases where the lack of controllability occurs can be seen as isolated anomalies. However, those phenomena give us important information on the systems. In particular, any method insensible to the value of those constants cannot control or stabilize the system when acting from the corresponding control input where trouble appears. In all of these cases, for both the KdV and the KS equations, the space of uncontrollable states is finite dimensional, and therefore, some

methods coming from the control of ordinary differential equations can be applied.

General Definitions

Infinite-dimensional control systems described by PDEs have attracted a lot of attention since the 1970s. In this framework, the state of the control system is given by the solution of an evolution PDE. This solution can be seen as a trajectory in an infinite-dimensional Hilbert space H , for instance, the space of square-integrable functions or some Sobolev space. Thus, for any time t , the state belongs to H . Concerning the control input, this is either an internal force distributed in the domain or a punctual force localized within the domain or some boundary data as considered in this article. For any time t , the control belongs to a control space U , which can be, for instance, the space of bounded functions. The main control properties to be mentioned in this article are controllability, stability, and stabilization. A control system is said to be exactly controllable if the system can be driven from any initial state to another one in finite time. This kind of properties holds, for instance, for hyperbolic system as the wave equation. The notion of null controllability means that the system can be driven to the origin from any initial state. The main example for this property is the heat equation, which presents regularizing effects. Even if the initial data is discontinuous, right after $t = 0$, the solution of the heat equation becomes very smooth, and therefore, it is not possible to impose a discontinuous final state. A system is said to be asymptotically stable if the solutions of the system without any control converge as the time goes to infinity to a stationary solution of the PDE. When this convergence holds with a control depending at each time on the state of the system (feedback control), the system is said to be stabilizable by means of a feedback control law.

All these properties have local versions when a smallness condition for the initial and/or the final state is added. This local character is normally due to the nonlinearity of the system.

The KdV Equation

The classical approach to deal with nonlinearities is first to linearize the system around a given state or trajectory, then to study the linear system, and finally to go back to the nonlinear one by means of an inversion argument or a fixed-point theorem. Linearizing (1) around the origin, we get the equation

$$y_t + y_x + y_{xxx} = 0, \quad (3)$$

which can be studied on a finite interval $[0, L]$ under the following three boundary conditions:

$$\begin{aligned} y(t, 0) = h_1(t), \quad y(t, L) = h_2(t), \\ \text{and} \quad y_x(t, L) = h_3(t). \end{aligned} \quad (4)$$

Thus, viewing $h_1(t)$, $h_2(t)$, $h_3(t) \in \mathbb{R}$ as controls and the solution $y(t, \cdot) : [0, L] \rightarrow \mathbb{R}$ as the state, we can consider the linear control system (3)–(4) and the nonlinear one (1), (2), (3), and (4).

We will report on the role of each input control when the other two are off. The tools used are mainly the duality controllability-observability, Carleman estimates, the multiplier method, the compactness-uniqueness argument, the backstepping method, and fixed-point theorems. Surprisingly, the control properties of the system depend strongly on the location of the controls.

Theorem 1 *The linear KdV system (3)–(4) is:*

1. *Null-controllable when controlled from h_1 (i.e., $h_2 = h_3 = 0$) (Glass and Guerrero 2008; Xiang 2019).*
2. *Exactly controllable when controlled from h_2 (i.e., $h_1 = h_3 = 0$) if and only if L does not belong to a set O of critical lengths defined in Glass and Guerrero (2010).*
3. *Exactly controllable when controlled from h_3 (i.e., $h_1 = h_2 = 0$) if and only if L does not belong to a set of critical lengths N defined in Rosier (1997).*
4. *Asymptotically stable to the origin if $L \notin N$ and no control is applied (Perla 2002).*

5. *Stabilizable by means of a feedback law using either h_1 only (i.e., $h_2 = h_3 = 0$) (Cerpa and Coron 2013; Xiang 2018) or h_2 and h_3 (i.e., $h_1 = 0$) (Özsari and Batal 2019). If $L \notin N$, then the stabilization is obtained using h_3 only (Coron and Lü 2014).*

If $L \in N$ or $L \in O$, one says that L is a critical length since the linear control system (3)–(4) loses controllability properties when only one control input is applied. In those cases, there exists a finite-dimensional subspace of $L^2(0, L)$ which is unreachable from 0 for the linear system. The sets N and O contain infinitely many critical lengths, but they are countable sets.

When one is allowed to use more than one boundary control input, there is no critical spatial domain, and the exact controllability holds for any $L > 0$. This is proved in Zhang (1999) when three boundary controls are used. The case of two control inputs is solved in Rosier (1997), Glass and Guerrero (2010), and Cerpa et al. (2013).

Previous results concern the linearized control system. Considering the nonlinearity yy_x , we obtain the original KdV control system and the following results.

Theorem 2 *The nonlinear KdV system (1) (2), (3), and (4) is:*

1. *Locally null-controllable when controlled from h_1 (i.e., $h_2 = h_3 = 0$) (Glass and Guerrero 2008).*
2. *Locally exactly controllable when controlled from h_2 (i.e., $h_1 = h_3 = 0$) if L does not belong to the set O of critical lengths (Glass and Guerrero 2010).*
3. *Locally exactly controllable when controlled from h_3 (i.e., $h_1 = h_2 = 0$). If L belongs to the set of critical lengths N , then a minimal time of control may be required (Cerpa 2014).*
4. *Asymptotically stable to the origin if $L \notin N$ and no control is applied (Perla 2002). For some lengths $L \in N$, the asymptotical stability has been proven in Chu et al. (2015) and Tang et al. (2018).*
5. *Locally stabilizable by means of a feedback law using either h_1 only (i.e., $h_2 = h_3 = 0$) (Cerpa and Coron 2013; Xiang 2018) or*

h_2 and h_3 (i.e., $h_1 = 0$) (Özsari and Batal 2019). If $L \notin N$, then the local stabilization is obtained using h_3 only (Coron et al. 2017; Coron and Lü 2014).

Item 2 in Theorem 2 is a truly nonlinear result obtained by applying a power series method introduced in Coron and Crépeau (2004). Stability results in Chu et al. (2015) and Tang et al. (2018) also use nonlinear methods. All other items are implied by perturbation arguments based on the linear control system. The related control system formed by (1) with boundary controls

$$\begin{aligned} y(t, 0) &= h_1(t), & y_x(t, L) &= h_2(t), \\ \text{and } y_{xx}(t, L) &= h_3(t) \end{aligned} \quad (5)$$

is studied in Cerpa et al. (2013) and Guilleron (2014). The same phenomenon of critical lengths appears.

The KS Equation

Applying the same strategy than for KdV, we linearize (2) around the origin to get the equation

$$u_t + u_{xxx} + \lambda u_{xx} = 0, \quad (6)$$

which can be studied on the finite interval $[0, 1]$ under the following four boundary conditions:

$$\begin{aligned} u(t, 0) &= v_1(t), & u_x(t, 0) &= v_2(t), \\ u(t, 1) &= v_3(t), & \text{and } u_x(t, 1) &= v_4(t). \end{aligned} \quad (7)$$

Thus, viewing $v_1(t), v_2(t), v_3(t), v_4(t) \in \mathbb{R}$ as controls and the solution $u(t, \cdot) : [0, 1] \rightarrow \mathbb{R}$ as the state, we can consider the linear control system (6)–(7) and the nonlinear one (2)–(7). The role of the parameter λ is crucial. The KS equation is parabolic and the eigenvalues of system (6)–(7) with no control ($v_1 = v_2 = v_3 = v_4 = 0$) go to $-\infty$. If λ increases, then the eigenvalues move to the right. When $\lambda > 4\pi^2$, the system becomes unstable because there are a finite

number of positive eigenvalues. In this unstable regime, the system loses control properties for some values of λ .

Theorem 3 *The linear KS control system (6)–(7) is:*

1. *Null-controllable when controlled from v_1 and v_2 (i.e., $v_3 = v_4 = 0$). The same is true when controlling v_3 and v_4 (i.e., $v_1 = v_2 = 0$) (Lin 2002; Cerpa and Mercado 2011).*
2. *Null-controllable when controlled from v_2 (i.e., $v_1 = v_2 = v_3 = 0$) if and only if λ does not belong to a countable set M defined in Cerpa (2010).*
3. *Null-controllable when controlled from v_1 (i.e., $v_2 = v_3 = v_4 = 0$) if and only if λ does not belong to a countable set M' defined in Cerpa et al. (2017).*
4. *Asymptotically stable to the origin if $\lambda < 4\pi^2$ and no control is applied (Liu and Krstic 2001).*
5. *Stabilizable by means of a feedback law using v_2 only (i.e., $v_2 = v_3 = v_4 = 0$) if and only if $\lambda \notin M$ (Cerpa 2010).*

In the critical case $\lambda \in M$, the linear system is not null-controllable anymore if we control v_2 only (item 3 in Theorem 3). The space of noncontrollable states is finite dimensional. To obtain the null controllability of the linear system in these cases, we have to add another control. Controlling with v_2 and v_4 does not improve the situation in the critical cases. Unlike that, the system becomes null-controllable if we can act on v_1 and v_2 . This result with two input controls has been proved in Lin (2002) for the case $\lambda = 0$ and in Cerpa and Mercado (2011) in the general case (item 3 in Theorem 3).

It is known from Liu and Krstic (2001) that if $\lambda < 4\pi^2$, then the system is exponentially stable in $L^2(0, 1)$. On the other hand, if $\lambda = 4\pi^2$, then zero becomes an eigenvalue of the system, and therefore the asymptotic stability fails. When $\lambda > 4\pi^2$, the system has positive eigenvalues and becomes unstable. In order to stabilize this system, a finite-dimensional-based feedback law can be designed by using the pole placement method (item 3 in Theorem 3).

Previous results concern the linearized control system. If we add the nonlinearity uu_x , we obtain the original KS control system and the following results.

Theorem 4 *The KS control system (2)–(7) is:*

1. *Locally null-controllable when controlled from v_1 and v_2 (i.e., $v_3 = v_4 = 0$). The same is true when controlling v_3 and v_4 (i.e., $v_1 = v_2 = 0$) (Cerpa and Mercado 2011).*
2. *Locally null-controllable when controlled from v_2 (i.e., $v_1 = v_2 = v_3 = 0$) if λ does not belong to a countable set M defined in Cerpa (2010). This result is due to Takahashi (2017).*
3. *Asymptotically stable to the origin if $\lambda < 4\pi^2$ and no control is applied (Liu and Krstic 2001).*

There are less results for the nonlinear systems than for the linear one. This is due to the fact that the spectral techniques used to study the linear system with only one control input are not always robust enough to deal with perturbations in order to address the nonlinear control system. One important exception is the result in item 4. When considering the KS equation with boundary conditions

$$\begin{aligned} u(t, 0) &= v_1(t), & u_{xx}(t, 0) &= v_2(t), \\ u(t, 1) &= v_3(t), & \text{and } u_{xx}(t, 1) &= v_4(t), \end{aligned} \quad (8)$$

we find stabilization results in Coron and Lü (2015) and cost-of-control results in Carreño (2016).

Summary and Future Directions

The KdV and the KS equations possess both noncontrol results when one boundary control input is applied. This is due to the fact that both are higher-order equations, and therefore, when posed on a bounded interval, more than one boundary condition should be imposed at

the same point. The KdV equation is exact controllable when acting from the right and null-controllable when acting from the left. On the other hand, the KS equation, being parabolic as the heat equation, is not exact controllable but null-controllable. Most of the results are implied by the behaviors of the corresponding linear system, which are very well understood.

For the KdV equation, the main directions to investigate at this moment are the controllability and the stability for the nonlinear equation in critical domains. Among others, some questions concerning controllability, minimal time of control, and decay rates for the stability are open. Regarding the KS equation, there are few results for the nonlinear system with one control input even if we are not in a critical value of the anti-diffusion parameter. In the critical cases, the controllability and stability issues are wide open.

In general, for PDEs, there are few results about delay phenomena, output feedback laws, adaptive control, and other classical questions in control theory. The existing results on these topics mainly concern the more popular heat and wave equations. As KdV and KS equations are one dimensional in space, many mathematical tools are available to tackle those problems. For all that, to our opinion, the KdV and KS equations are excellent candidates to continue investigating these control properties in a PDE framework, as shown in recent articles (Marx and Cerpa 2018; Baudouin et al. 2019; Guzmán et al. 2019).

Abstract

We review several universal lower bounds on statistical estimation, including deterministic bounds on unbiased estimators such as Cramér-Rao bound and Barankin-type bound, as well as Bayesian bounds such as Ziv-Zakai bound. We present explicit forms of these bounds, illustrate their usage for parameter estimation in Gaussian additive noise, and compare their tightness.

Keywords

Barankin-type bound · Cramér-Rao bound · Mean-squared error · Statistical estimation · Ziv-Zakai bound

Introduction

Statistical estimation involves inferring the values of parameters specifying a statistical model from data. The performance of a particular statistical algorithm is measured by the error between the true parameter values and those estimated by the algorithm. However, explicit forms of estimation error are usually difficult to obtain except for the simplest statistical models. Therefore, performance bounds are derived as a way of quantifying estimation accuracy while maintaining tractability.

In many cases, it is beneficial to quantify performance using universal bounds that are independent of the estimation algorithms and rely only upon the model. In this regard, universal lower bounds are particularly useful as it provides means to assess the difficulty of performing estimation for a particular model and can act as benchmarks to evaluate the quality of any algorithm: the closer the estimation error of the algorithm to the lower bound, the better the algorithm. In the following, we review three widely used universal lower bounds on estimation: Cramér-Rao bound (CRB), Barankin-type bound (BTB), and Ziv-Zakai bound (ZZB). These bounds find numerous applications in determining the performance of sensor arrays, radar, and nonlinear filtering; in benchmarking various algorithms; and in optimal design of systems.

Statistical Model and Related Concepts

To formalize matters, we define a statistical model for estimation as a family of parameterized probability density functions in $\mathbb{R}^N$: $\{p(x; \theta) : \theta \in \Theta \subset \mathbb{R}^d\}$. We observe a realization of $x \in \mathbb{R}^N$ generated from a distribution $p(x; \theta)$, where $\theta \in \Theta$ is the true parameter to be estimated from data x . Though we assume a single observation x , the model is general enough to encompass multiple independent, identically distributed samples (i.i.d.) by considering the joint probability distribution.

An estimator of θ is a measurable function of the observation $\hat{\theta}(x) : \mathbb{R}^N \rightarrow \Theta$. An unbiased estimator is one such that

$$\mathbb{E}_\theta \left\{ \hat{\theta}(x) \right\} = \theta, \forall \theta \in \Theta. \quad (1)$$

Here we used the subscript θ to emphasize that the expectation is taken with respect to $p(x; \theta)$. We focus on the performance of unbiased estimators in this entry. There are various ways to measure the error of the estimator $\hat{\theta}(x)$. Two typical ones are the error covariance matrix:

$$\mathbb{E}_\theta \left\{ (\hat{\theta} - \theta)(\hat{\theta} - \theta)^T \right\} = \text{Cov}(\hat{\theta}), \quad (2)$$

where the equation holds only for unbiased estimators, and the mean-squared error (MSE):

$$\mathbb{E}_\theta \left\{ \|\hat{\theta}(x) - \theta\|_2^2 \right\} = \text{trace} \left(\mathbb{E}_\theta \left\{ (\hat{\theta} - \theta)(\hat{\theta} - \theta)^T \right\} \right). \quad (3)$$

Example 1 (Signal in additive Gaussian noise (SAGN)) To illustrate the usage of different estimation bounds, we use the following statistical model as a running example:

$$x_n = s_n(\theta) + w_n, n = 0, \dots, N-1. \quad (4)$$

Here $\theta \in \Theta \subset \mathbb{R}$ is a scalar parameter to be estimated and the noise w_n follows i.i.d. Gaussian distribution with mean 0 and known variance σ^2 . Therefore, the density function for x is

$$\begin{aligned} p(x; \theta) &= \prod_{n=0}^{N-1} \frac{1}{\sqrt{2\pi}\sigma} \exp \left\{ -\frac{(x_n - s_n(\theta))^2}{2\sigma^2} \right\} \\ &= \frac{1}{(\sqrt{2\pi}\sigma)^N} \exp \left\{ -\sum_{n=0}^{N-1} \frac{(x_n - s_n(\theta))^2}{2\sigma^2} \right\}. \end{aligned}$$

In particular, we consider the frequency estimation problem where $s_n(\theta) = \cos(2\pi n\theta)$ with $\Theta = [0, \frac{1}{4})$.

Cramér-Rao Bound

The Cramér-Rao bound (CRB) (Kay 2001a; Van Trees 2001; Stoica and Nehorai 1989) is arguably the most well-known lower bounds on estimation. Define the Fisher information matrix $I(\theta)$ via

$$\begin{aligned} I_{i,j}(\theta) &= \mathbb{E}_{\theta} \left\{ \frac{\partial}{\partial \theta_i} \log p(x; \theta) \frac{\partial}{\partial \theta_j} \log p(x; \theta) \right\} \\ &= -\mathbb{E}_{\theta} \left\{ \frac{\partial^2}{\partial \theta_i \partial \theta_j} \log p(x; \theta) \right\}. \end{aligned}$$

Then for *any* unbiased estimator $\hat{\theta}$, the error covariance matrix is bounded by

$$\mathbb{E}_{\theta} \left\{ (\hat{\theta} - \theta)(\hat{\theta} - \theta)^T \right\} \succeq [I(\theta)]^{-1}, \quad (5)$$

where $A \succeq B$ for two symmetric matrices means $A - B$ is positive semidefinite. The inverse of the Fisher information matrix $\text{CRB}(\theta) = [I(\theta)]^{-1}$ is called the Cramér-Rao bound.

When θ is scalar, $I(\theta)$ measures the expected sensitivity of the density function with respect to changes in the parameter. A density family that is more sensitive to parameter changes (larger $I(\theta)$) will generate observations that look more different when the true parameter varies, making it easier to estimate (smaller error).

Example 2 For the SAGN model (4), the CRB is

$$\text{CRB}(\theta) = I(\theta)^{-1} = \frac{\sigma^2}{\sum_{n=0}^{N-1} \left[\frac{\partial s_n(\theta)}{\partial \theta} \right]^2}. \quad (6)$$

The inverse dependence on the ℓ_2 norm of signal derivative suggests that signals more sensitive to parameter change are easier to estimate.

For the frequency estimation problem with $s_n(\theta) = \cos(2\pi n\theta)$, the CRB as a function of θ is plotted in Fig. 1.

There are many modifications of the basic CRB such as the posterior CRB (Van Trees 2001; Tichavsky et al. 1998), the hybrid CRB (Rockah and Schultheiss 1987), the modified CRB (D'Andrea et al. 1994), the concentrated

Bounds on Estimation, Fig. 1 Cramér-Rao bound on frequency estimation: $N = 5$ vs. $N = 10$

CRB (Hochwald and Nehorai 1994), and constrained CRB (Stoica and Ng 1998; Gorman and Hero 1990; Marzetta 1993). The posterior CRB takes into account the prior information of the parameters when they are modeled as random variables, while the hybrid CRB considers the case that the parameters contain both random and deterministic parts. The modified CRB and the concentrated CRB focus on handling nuisance parameters in a tractable manner. The application of these CRBs requires a regular parameter space (e.g., an open set in $\mathbb{R}^d$). However, in many cases, the parameter space Θ is a low-dimensional manifold in $\mathbb{R}^d$ specified by equalities and inequalities. In this case, the constrained CRB provides tighter lower bounds by incorporating knowledge of the constraints.

Barankin Bound

CRB is a local bound in the sense that it involves only local properties (the first or second order derivatives) of the log-likelihood function. So if two families of log-likelihood functions coincide at a region near θ^0 , the CRB at θ^0 would be the same, even if they are drastically different in other regions of the parameter space.

However, the entire parametric space should play a role in determining the difficulty of parameter estimation. To see this, imagine that there are two statistical models. In the first model there is another point $\theta^1 \in \Theta$ such that the likelihood family $p(x; \theta)$ behaves similarly around θ^0 and θ^1 , but these two points are not in neighborhoods of each other. Then it would be difficult to distinguish these two points for any estimation algorithm, and the estimation performance for the first statistical model would be bad (an extreme case is $p(x; \theta^0) \equiv p(x; \theta^1)$ in which case the model is non-identifiable; more discussions on identifiability and Fisher information matrix can be found in Hochwald and Nehorai (1997)). In the second model, we remove the point θ^1 and its near neighborhood from Θ , then the performance should get better. However, CRB for both models would remain the same whether we exclude θ^1 from Θ or not. As a matter of fact, $\text{CRB}(\theta^0)$ uses only the fact that the estimator is unbiased in a neighborhood of the true parameter θ^0 .

Barankin bound addresses CRB's shortcoming of not respecting the global structure of the statistical model by introducing finitely many test points $\{\theta^i, i = 1, \dots, M\}$ and ensures that the estimator is unbiased at the neighborhood of θ^0 as well as these test points (Forster and Larzabal 2002). The original Barankin bound (Barankin 1949) is derived for scalar parameter $\theta \in \Theta \subset \mathbb{R}$ and any unbiased estimator $\widehat{g(\theta)}$ for a function $g(\theta)$:

$$\mathbb{E}_\theta (\widehat{g(\theta)} - g(\theta))^2 \geq \sup_{M, \theta^i, a^i} \frac{\left[\sum_{m=1}^M a^i (g(\theta^i) - g(\theta)) \right]^2}{\mathbb{E}_\theta \left[\sum_{m=1}^M a^i \frac{p(x; \theta^i)}{p(x; \theta)} \right]^2} \quad (7)$$

Using (7), we can derive a Barankin-type bound on the error covariance matrix of any unbiased estimator $\hat{\theta}(x)$ for a vector parameter $\theta \in \Theta \subset \mathbb{R}^d$ (Forster and Larzabal 2002):

$$\mathbb{E}_\theta \left\{ (\hat{\theta} - \theta)(\hat{\theta} - \theta)^T \right\} \geq \Phi(B - 11^T)^{-1} \Phi^T, \quad (8)$$

where the matrices are defined via

$$B_{i,j} = \mathbb{E}_\theta \left\{ \frac{p(x; \theta^i)}{p(x; \theta)} \frac{p(x; \theta^j)}{p(x; \theta)} \right\}, \quad 1 \leq i, j \leq M,$$

$$\Phi = [\theta^1 - \theta \dots \theta^M - \theta]$$

and 1 is the vector in $\mathbb{R}^M$ with all ones. Note that we have used θ^i with a superscript to denote different points in Θ , while θ_i with a subscript to denote the i th component of a point θ .

Since the bound (8) is valid for any M and any choice of test points $\{\theta^i\}$, we obtain the tightest bound by taking the supremum over all finite families of test points. Note that when we have d test points that approach θ in d linearly independent directions, the Barankin-type bound (8) converges to the CRB. If we have more than d test points, however, the Barankin-type bound is always not worse than the CRB. Particularly, the Barankin-type bound is much tighter in the regime of low signal-to-noise ratio (SNR) and small number of measurements, which allows one to investigate the “threshold” phenomena as shown in the next example.

Example 3 For the SAGN model, if we have M test points, the elements of matrix B are of the following form:

$$B_{i,j} = \exp \left\{ \frac{1}{\sigma^2} \sum_{n=0}^{N-1} [s_n(\theta^i) - s_n(\theta)] [s_n(\theta^j) - s_n(\theta)] \right\}$$

In most cases, it is extremely difficult to derive an analytical form of the Barankin bound by optimizing with respect to M and the test points $\{\theta^j\}$. In Fig. 2, we plot the Barankin-type bounds for $s_n(\theta) = \cos(2\pi n\theta)$ for $M = 10$ randomly selected test points. We observe that Barankin-type bound is tighter than the CRB when SNR is small. There is a SNR region around 0 dB that the Barankin-type bound drops drastically. This is usually called the “threshold” phenomenon. Practical systems operate much better in the region above the threshold.

Bounds on Estimation, Fig. 2 Cramér-Rao bound vs. Barankin-type bound on frequency estimation when $\theta^0 = 0.1$. The BTB is obtained using $M = 10$ uniform random points

The basic CRB and BTB belong to the family of deterministic “covariance inequality” bounds in the sense that the unknown parameter is assumed to be a *deterministic* quantity (as opposed to a *random* quantity). Additionally, both bounds work only for unbiased estimators, making them inappropriate performance indicators for biased estimators such as many regularization-based estimators.

Ziv-Zakai Bound

In this section, we introduce the Ziv-Zakai bound (ZZB) (Bell et al. 1997) that is applicable to any estimator (not necessarily unbiased). Unlike the CRB and BTB, the ZZB is a Bayesian bound and the errors are averaged by the prior distribution $p_\theta(\phi)$ of the parameter. For any $a \in \mathbb{R}^d$, the ZZB states that

$$a^T \mathbb{E} \left\{ (\hat{\theta}(x) - \theta)(\hat{\theta}(x) - \theta)^T \right\} a \geq \frac{1}{2} \int_0^\infty \mathcal{V} \left\{ \max_{\delta: a^T \delta = h} \left[\int_{\mathbb{R}^d} (p_\theta(\phi) + p_\theta(\phi + \delta)) \right. \right. \\ \left. \left. \text{times } P_{\min}(\phi, \phi + \delta) d\phi \right] \right\} h dh,$$

where the expectation is taken with respect to the joint disunity $p(x; \theta)p_\theta(\phi)$, $\mathcal{V}\{q(h)\} = \max_{r \geq 0} q(h + r)$ is the valley-filling function,

and $P_{\min}(\phi, \phi + \delta)$ is the minimal probability of error for the following binary hypothesis testing problem:

$$\begin{aligned} H_0 : \theta &= \phi; & x &\sim p(x; \phi) \\ H_1 : \theta &= \phi + \delta; & x &\sim p(x; \phi + \delta) \end{aligned}$$

with

$$\begin{aligned} \Pr(H_0) &= \frac{p_\theta(\phi)}{p_\theta(\phi) + p_\theta(\phi + \delta)} \\ \Pr(H_1) &= \frac{p_\theta(\phi + \delta)}{p_\theta(\phi) + p_\theta(\phi + \delta)}. \end{aligned}$$

Example 4 For the ASGN model, we assume a uniform prior probability, i.e., $p_\theta(\phi) = 4, \phi \in [0, 1/4]$. The ZZB simplifies to

$$\begin{aligned} \mathbb{E} \left\{ \|\hat{\theta}(x) - \theta\|_2^2 \right\} &\geq \\ \frac{1}{2} \int_0^{\frac{1}{4}} \mathcal{V} \left\{ \left[\int_0^{\frac{1}{4}-h} 8 P_{\min}(\phi, \phi + h) d\phi \right] \right\} h dh. \end{aligned}$$

The binary hypothesis testing problem is to decide which one of two signals is buried in additive Gaussian noise. The optimal detector with minimal probability of error is the minimum distance receiver (Kay 2001b), and the associated probability of error is

$$\begin{aligned} P_{\min}(\phi, \phi + h) &= \\ &= Q \left(\frac{1}{2} \sqrt{\frac{\sum_{n=0}^{N-1} (s_n(\phi) - s_n(\phi + h))^2}{\sigma^2}} \right), \end{aligned}$$

where $Q(h) = \int_h^\infty \frac{1}{\sqrt{2\pi}} e^{-\frac{t^2}{2}} dt$. For the frequency estimation problem, we numerically estimate the integral and plot the resulting ZZB in Fig. 3 together with the mean-squared error for the maximum likelihood estimator (MLE).

Bounds on Estimation, Fig. 3 Ziv-Zakai bound vs. maximum likelihood estimator for frequency estimation

Summary and Future Directions

We have reviewed several important performance bounds on statistical estimation problems, particularly, the Cramér-Rao bound, the Barankin-type bound, and the Ziv-Zakai bound. These bounds provide a universal way to quantify the performance of statistically modeled physical systems that is independent of any specific algorithm.

Future directions of performance bounds on estimation include deriving tighter bounds, developing computational schemes to approximate existing bounds in a tractable way, and applying them to practical problems.

Building Comfort and Environmental Control

John T. Wen

Electrical, Computer, and Systems Engineering (ECSE), Rensselaer Polytechnic Institute, Troy, NY, USA

Abstract

Heating, ventilation, and air condition (HVAC) systems regulate building temperature and humidity distributions. Sound HVAC system operation is critical for maintaining the comfort level of building occupants, providing the proper operating condition for building equipments and contents, and in general achieving a healthy and safe building environment. HVAC is also a major energy consumer. Balancing comfort and environmental control versus energy consumption is a major theme in building HVAC control. This entry describes the modeling of the HVAC system dynamics in buildings, the HVAC control problem addressing human comfort and energy consumption, and the adaptation to variations in the ambient operating condition.

Keywords

Human comfort control · Temperature control · Humidity control · HVAC control · Intelligent building controls

Introduction

The building environment affects its occupants through temperature, humidity, lighting, air quality, noise, etc. Temperature and humidity together are called the *thermohygroscopic* condition. The

building heating, ventilation, and air conditioning (HVAC) system regulates temperature and humidity by adjusting the supply air with given temperature and humidity to achieve the desired operating condition within the building. Residential and commercial buildings account for nearly 30% of the US energy consumption (U.S. Energy Information Administration 2019a), of which more than 50% is due to the HVAC operation (U.S. Energy Information Administration 2019b). Balancing human comfort and energy efficiency is a key building control objective.

A schematic of the HVAC system for a multi-zone building is depicted in Fig. 1a. A mixture of outside air and return air is heated or cooled and then supplied to each zone. The ratio between the outside air and return air is determined by the consideration of air quality and energy consumption. Thermostats and humidistats allow the setting of the target temperature and humidity and adjust the supplied air based on the measured temperature and humidity to achieve the specified conditions.

Moist air is characterized by its heat and moisture content. The psychrometric chart, shown in Fig. 1b, depicts the relationship of various thermodynamical properties, including the dry bulb temperature (air temperature), specific humidity (amount of moisture content in a unit volume of moist air), specific enthalpy (amount of heat in a unit volume of moist air), and relative humidity (amount of moisture in air expressed as a percentage of the amount needed for saturation) (Lide 2005; Urieli 2010). A typical subjective comfort zone is shown as the shaded region resulting from bounds on temperature, relative humidity, and specific enthalpy. Energy consumption of the HVAC system is determined by the cooling and heating of the supplied air, and the energy needed to deliver the supplied air into the zones by using blower fans or radiator pumps. The source of cooling is typically from an air conditioning system which operates on a vapor compression cycle (VCC). The design for such systems is usually for the steady state operation which is well understood. However, for systems with significant transients, e.g., short duration load demands, say during a heat wave, there may need to be

Building Comfort and Environmental Control, Fig. 1 HVAC system for building occupant comfort control. (a) Schematics of a building HVAC system. The state of the i th zone, given by (w_i, T_i) , is affected by the state of adjacent zones, (w_j, T_j) , the ambient condition (w_∞, T_∞) , the properties of the supply air (w_s, T_s) and flow rate

$\dot{m}_i$. (b) Psychrometric chart showing relationship between thermodynamical properties of moist air, including the dry bulb temperature (horizontal axis), specific humidity (vertical axis), specific enthalpy (green dash line), and relative humidity (blue curves). The shaded region indicates a typical comfort zone for human occupants

active control of these subsystems (Rasmussen et al. 2018).

HVAC Dynamical Model

Building dynamics as related to occupancy comfort and environmental condition is characterized by the heat and moisture transfer. The underlying physics is governed by the conservation of mass and energy. These are nonlinear partial differential equations that require the use numerical approximation for their solution (such as computation fluid dynamics) (U.S. Department of Energy 2019). Such models are useful for design and assessment, but are not suitable for control design due to their complexity and computation overhead. For the HVAC control system analysis and design, the building dynamics is typically modeled as a lumped parameter system. In this case, the building is divided into *zones* with the average temperature and humidity characterizing the state of the zone (Goyal and Barooah 2012; Okaeme et al. 2018).

The humidity dynamics in a zone is governed by the mass transfer between zones (including the ambient). Denote the mass of dry air in the i th zone by the constant M_i . Let the humidity ratio of the zone be w_i which is the amount of moisture in a unit volume of dry air. The mass balance is governed by moisture diffusion (Fick's Law):

$$M_i \dot{w}_i = - \sum_j G_{ij}(w_i - w_j) - G_{i0}(w_i - w_\infty) + v_{m_i} \quad (1)$$

where the sum is over all neighboring zones, G_{ij} is the mass conductance between zones i and j , G_{i0} is the mass conductance to the ambient, w_∞ is the humidity ratio of the ambient, and v_{m_i} is the moisture injected by the supply air into the i th zone: $v_{m,i} = \dot{m}_i \frac{(w_s - w_i)}{1 + w_s} + v_{m,d}$ with $\dot{m}_i$ as the mass flow rate of the supply air, w_s the humidity ratio of the supply air, and $v_{m,d}$ the exogenous moisture input, e.g., occupant body evaporation.

Similarly, temperature is governed by the heat and mass transfer between zones (including the ambient). For heat transfer, each zone is

considered as a thermal capacitance (sometimes called thermal mass or thermal inertia) connected to other thermal capacitances through thermal conductances. Let β be the latent heat of vaporization for water, the energy balance equation for the i th zone based on heat conduction is

$$C_i \dot{T}_i = - \sum_j K_{ij}(T_i - T_j) - K_{i0}(T_i - T_\infty) + v_{e_i} + \beta G_{i0}(w_i - w_\infty) + \beta \sum_j G_{ij}(w_i - w_j) \quad (2)$$

where $C_i = c_p M_i$ is the thermal capacitance of the i th zone (c_p is the specific heat), K_{ij} is the thermal conductance between zones i and j , j sums over all zones adjacent to zone i , and v_{e_i} is the heat input into the zone: $v_{e,i} = \dot{m}_i c_p (T_s - T_i) + v_{e,d}$ with T_s the supplied air temperature and $v_{e,d}$ the exogenous heat input, e.g., solar heat gain, heat from equipment and human occupants, etc. Sometimes thermal capacitances in walls are also modeled, e.g., the commonly used 3R2C model considers a wall as two thermal capacitors sandwiched between three thermal resistors (thermal resistance is the reciprocal to thermal conductance).

The humidity model of a multi-zone building may be represented as a moisture exchange graph with each zone as nodes and mass conductors as links between adjacent nodes that allow mass transfer. Similarly, the heat transfer is represented as a thermal graph with thermal capacitors as nodes and thermal conductors as links between nodes. The humidity and thermal equations for a multi-zone building may then be written in the following compact form:

$$M \dot{w} = -LGL^T w + B_{m0} w_\infty + v_m \quad (3a)$$

$$C \dot{T} = -DKD^T T + \beta LGL^T w - \beta B_{m0} w_\infty + B_{e0} T_\infty + v_e \quad (3b)$$

where (w, T) denote the vectors of humidity ratios and temperatures (including zone and wall temperatures), (v_m, v_e) are the moisture and heat input into the room, M and C are diagonal

positive definite matrices consisting of zone air masses and thermal capacitances, G and K are diagonal positive definite matrices consisting of link mass and thermal conductances, B_{m0} and $B_{e,0}$ are column vectors with mass and thermal conductances connecting nodes to the ambient. For the moisture exchange graph, L is the incidence matrix and LGL^T is the weight Laplacian of the graph. For the thermal graph, D is the incidence matrix and DKD^T is the weighted Laplacian (Deng et al. 2010; Mukherjee et al. 2012).

HVAC Control Systems

The HVAC system of a multi-zone building viewed in the control context may be depicted as in Fig. 2. As described in the modeling section above, the state of the building consists of temperatures in the thermal capacitors and humidity ratios in all zones. The control input may be the heat and moisture delivered or removed from each zone, or the mass flow rate of the supplied air. In some cases, temperature and humidity of the supplied air are independently controlled (e.g., with heater/air conditioner or humidifier/dehumidifier). Zone temperature and humidity are measured through thermometers and hygrometers. These measurements are used in thermostat and humidistat to maintain the specified temperature and humidity set points in all zones by regulating the heat and moisture injection/removal in the zone. The HVAC control

problem is to use the control input to achieve the target temperature and humidity profiles. The challenge of the control problem include:

1. Coupled dynamics, i.e., each zone is affected by adjacent zones;
2. Unknown, uncertain, or time-varying model parameters (e.g., opening of windows or doors);
3. Time-varying exogenous inputs, e.g., ambient (outdoor) weather condition, heat and moisture from occupants and equipment within the zone, solar heat gain, etc. Some of the variation may be known ahead of time, e.g., through the weather forecast or room usage pattern. This knowledge may be incorporated into a predictive control strategy.

Existing commercial off-the-shelf building temperature and humidity control systems typically treat each zone individually, and apply an on-off control strategy based on the measured temperature and humidity in that zone. Hysteresis or dead zone is applied to the temperature and humidity error signal to avoid chattering in the control signal. Supervisory control schedules the temperature and humidity set points based on room usage to reduce energy consumption and enhance occupant comfort. For example, the temperature set point in an office space may be raised before the start of the work day and lowered during the off-hours.

Most of the building HVAC control literature deals with temperature control problem, with

Building Comfort and Environmental Control,

Fig. 2 HVAC control architecture of a multi-zone building. The humidity ratios and temperatures in all the zones are denoted by vectors (w, T) . The outside humidity ratio and temperature are denoted by (w_∞, T_∞)

the latent heat of vaporization treated as a disturbance in the temperature dynamics (3a). Numerous advanced control strategies have been proposed to address the multi-zone coupling in the dynamical model and exogenous heat input variation (Afram and Janabi-Sharifi 2014). They span the range of control methodologies, including classical linear control, advanced nonlinear control, and logic and neural network-based control. Robust, adaptive, or learning control has all been proposed to address the uncertain and possibly time-varying model parameters. Building temperature dynamics modeled with thermal resistance-capacitance (RC) elements possesses an inherent passivity property, as in passive electrical circuits (inductor-resistor-capacitor) or passive mechanical structures (mass-spring-damper). If the product of the input and output of a system is interpreted as the power delivered to the system, then for a passive system, the energy is always delivered to the system, meaning that the system either conserves or dissipates energy. For the building thermal model, the rate of the heat injection into the zones, v_e , and temperatures in the zones, $B^T T$, form a strictly passive input/output pairs (similar to voltage and current into a passive circuit, or collocated force and velocity in a mechanical structure) (Mukherjee et al. 2012). It follows from the passivity theorem that any passive output feedback would ensure stability. This means the existing decentralized control that ignores the multi-zone coupling is always stabilizing. Using this passivity framework, it may be shown that under constant but unknown exogenous input condition, high-gain feedback such as an on-off type of control, or integral feedback to adaptively remove any steady state bias, would asymptotically converge to a constant set point even in the complete absence of any model parameter information. When the exogenous input is time-varying, e.g., fluctuating occupancy and equipment usage or changing weather condition, feedback control alone could result in significant errors, possibly leading to occupant discomfort and energy inefficiency. If this variation is known beforehand (e.g., through short-term weather forecast or known

zone occupancy schedule), it may be used as a feedforward to preemptively adjust the zone temperature to improve the temperature tracking accuracy (utilizing the building thermal capacitances). If the model information is available, at least approximately, it may be used in a finite horizon optimization, as in model predictive control (MPC) (Ma et al. 2012; Mirakhorli and Dong 2016), to take the ambient variation into account to minimize a combination of tracking error and energy consumption. The optimization approach also addresses actuator limits such as the allowable range of fan speed. If the optimization variable is the heat into each zone, the optimization becomes a linear programming problem. If the optimization variable is the mass flow rate (controlled through the fan speed), the resulting optimization is bilinear, and the problem may become nonconvex. The optimization problem may be solved in a distributed manner based on schemes such as alternating direction method of multipliers (ADMM) (Boyd 2018). This is particularly useful to balance the comfort preference of multiple users and the desire for low energy cost of the building operator (Gupta et al. 2015). Voting and auction type of schemes have also been proposed in a multiuser environment (Erickson and Cerpa 2012). When the exogenous input exhibits a certain known structure (e.g., cyclic variation of occupancy, weather pattern similar to the past), the Lyapunov function motivated by the passivity property allows adaptation or learning of the feedforward control (Peng et al. 2016; Minakais et al. 2019).

The passivity approach also extends to the control of both temperature and humidity (Okaeme et al. 2018). If heat and humidity into each zone are independently controlled with the rate of heat and moisture injection as input, the extension of the passivity approach is straightforward with the corresponding output to be zone temperature and humidity. If the mass flow rate is the input, then the temperature and humidity measurements need to be judiciously combined to form a passive output.

Summary and Future Directions

HVAC is an important component of the overall building control system. It affects occupant comfort, cost of building operation, and interacts with other building control subsystems such as air quality, noise, and lighting. Current trend in HVAC system design is to incorporate better modeling and data analytics to improve the understanding and prediction of building usage, human occupant preferences, and variations in the building environment. Toward this direction of intelligent building control, more sensors than ever are deployed in buildings, including stationary sensors such temperature and humidity sensors and mobile sensors such as human wearable devices. These sensors are networked together using Internet of Things (IoT) technologies to facilitate data collection and analysis, which in turn are used to guide building operation and decision-making. Buildings are also becoming more interactive, with users able to provide individual feedback on comfort and preference levels. In this highly interconnected scenario, occupant privacy and building security are key concerns; any building monitoring and data gathering system must provide sufficient safeguard.

Building Control Systems

James E. Braun

Purdue University, West Lafayette, IN, USA

Abstract

This entry provides an overview of systems and issues related to providing optimized

controls for commercial buildings. It includes a description of the evolution of the control systems over time, typical equipment and control variables, typical two-level hierarchal structure for feedback and supervisory control, definition of the optimal supervisory control problem, references to typical heuristic control approaches, and a description of current and future developments.

Keywords

Building automation systems (BAS) · Cooling plant optimization · Energy management and controls systems (EMCS) · Intelligent building controls

Introduction

Computerized control systems were developed in the 1980s for commercial buildings and are typically termed energy management and control systems (EMCS) or building automation systems (BAS). They have been most successfully applied to large commercial buildings that have hundreds of building zones and thousands of control points. Less than about 15 % of commercial buildings have EMCS, but they serve about 40 % of the floor area. Small commercial buildings tend not to have an EMCS, although there is a recent

trend towards the use of wireless thermostats with cloud-based energy management solutions.

EMCS architectures for buildings have evolved from centralized to highly distributed systems as depicted in Fig. 1 in order to reduce wiring costs and provide more modular solutions. The development of open communications protocols, such as BACNet, has enabled the use of distributed control devices from different vendors and improved the cost-effectiveness of ECMS. There has also been a recent trend towards the use of existing enterprise networks to reduce system installed costs and to more easily allow remote access and control from any Internet accessible device.

An EMCS for a large commercial building can automate the control of many of the building and system functions, including scheduling of lights and zone thermostat settings according to occupancy patterns. Security and fire safety systems tend to be managed using separate systems. In addition to scheduling, an EMCS manages the control of individual equipment and subsystems that provide heating, ventilation, and air conditioning of the building (HVAC). This control is achieved using a two-level hierarchical structure of local-loop and supervisory control. Local-loop control of individual set points is typically implemented using individual proportional-integral (PI) feedback algorithms that manipulate

Building Control Systems, Fig. 1 Evolution from centralized to distributed network architectures

individual actuators in response to deviations from the set points. For example, supply air temperature from a cooling coil is controlled by adjusting a valve opening that provides chilled water to the coil. The second level of supervisory control specifies the set points and other modes of operation that depend on time and external conditions.

Each local-loop feedback controller acts independently, but their performance can be coupled to other local-loop controllers if not tuned appropriately. Adaptive tuning algorithms have been developed in recent years to enable controllers to automatically adjust to changing weather and load conditions. There are typically a number of degrees of freedom in adjusting supervisory control set points over a wide range while still achieving adequate comfort conditions. Optimal control of supervisory set points involves minimizing a cost function with respect to the free variables and subject to constraints. Although model-based, control optimization approaches are not typically employed in buildings, they have been used to inform the development and assessment of some heuristic control strategies. Most commonly, strategies for adjusting supervisory control variables are established at the control design phase based on some limited analysis of the HVAC system and specified as a sequence of operations that is programmed into the EMCS.

Systems, Equipment, and Controls

The greatest challenges and opportunities for optimizing supervisory control variables exist for centralized cooling systems that are employed in large commercial buildings because of the large number of control variables and degrees of freedom along with utility rate incentives. A simplified schematic of a typical centralized cooling plant is shown in Fig. 2 with components grouped under air distribution, chilled water loop, chiller plant, and condenser water loop.

Typical **air distribution systems** include VAV (variable-air volume) boxes within the zones, air-handling units, ducts, and controls.

An air-handling unit (AHU) provides the primary conditioning, ventilation, and flow of air and includes cooling and heating coils, dampers, fans, and controls. A single air handler typically serves many zones and several air handlers are utilized in a large commercial building. For each AHU, outdoor ventilation air is mixed with return air from the zones and fed to the cooling coil. Outdoor and return air dampers are typically controlled using an economizer control that selects between minimum and maximum ventilation air depending upon the condition of the outside air. The cooling coil provides both cooling and dehumidification of the process air. The air outlet temperature from the coil is controlled with a local feedback controller that adjusts the flow of water using a valve. A supply fan and return fan (not shown in Fig. 2) provide the necessary air-flow to and from the zones. With a VAV system, zone temperature set points are regulated using a feedback controller applied to dampers within the VAV boxes. The overall air flow provided by the AHU is typically controlled to maintain a duct static pressure set point within the supply duct.

The **chilled water loop** communicates between the cooling coils within the AHUs and chillers that provide the primary source for cooling. It consists of pumps, pipes, valves, and controls. Primary/secondary chilled water systems are commonly employed to accommodate variable-speed pumping. In the primary loop, fixed-speed pumps are used to provide relatively constant chiller flow rates to ensure good performance and reduce the risk of evaporator tube freezing. Individual pumps are typically cycled on and off with a chiller that it serves. The secondary loop incorporates one or more variable-speed pumps that are typically controlled to maintain a set point for chilled water loop differential pressure between the building supplies and returns.

The primary source of cooling for the system is typically provided by one or more **chillers** that are arranged in parallel and have dedicated pumps. Each chiller has an on-board local-loop feedback controller that adjusts its cooling capacity to maintain a specified set point for chilled water supply temperature. Additional chiller con-

Building Control Systems, Fig. 2 Schematic of a chilled water cooling system

Control variables include the number of chillers operating and the relative loading for each chiller. The relative loading can be controlled for a given total cooling requirement by utilizing different chilled water supply set points for constant individual flow or by adjusting individual flows for identical set points. Chillers can be augmented with thermal storage to reduce the amount of chiller power required during occupied periods in order to reduce on-peak energy and power demand costs. The thermal storage medium is cooled during the unoccupied, nighttime period using the chillers when electricity is less expensive. During occupied times, a combination of the chillers and storage are used to meet cooling requirements. Control of thermal storage is defined by the manner in which the storage medium is charged and discharged over time.

The **condenser water loop** includes cooling towers, pumps, piping, and controls. Cooling towers reject energy to the ambient air through heat transfer and possibly evaporation (for wet towers). Larger systems tend to have multiple cooling towers with each tower having multiple cells that share a common sump with individual

fans having two or more speed settings. The number of operating cells and tower fan speeds are often controlled using a local-loop feedback controller that maintains a set point for the water temperature leaving the cooling tower. Typically, condenser water pumps are dedicated to individual chillers (i.e., each pump is cycled on and off with a chiller that it serves).

In order to better understand building control variables, interactions, and opportunities, consider how controls change in response to increasing building cooling requirements for the system of Fig. 2. As energy gains to the zones increase, zone temperatures rise in the absence of any control changes. However, zone feedback controllers respond to higher temperatures by increasing VAV box airflow through increased damper openings. This leads to reduced static pressure in the primary supply duct, which causes the AHU supply fan controller to create additional airflow. The greater airflow causes an increase in supply air temperatures leaving the cooling coils in the absence of any additional control changes. However, the supply air temperature feedback controllers respond by opening the cooling coil

valves to increase water flow and the heat transfer to the chilled water (the cooling load). For variable-speed pumping, a feedback controller would respond to decreasing pressure differential by increasing the pump speed. The chillers would then experience increased loads due to higher return water temperature and/or flow rate that would lead to increases in chilled water supply temperatures. However, the chiller controllers would respond by increasing chiller cooling capacities in order to maintain the chilled water supply set points (and match the cooling coil loads). In turn, the heat rejection to the condenser water loop would increase to balance the increased energy removed by the chiller, which would increase the temperature of water leaving the condenser. The temperature of water leaving the cooling tower would then increase due to an increase in its energy water temperature. However, a feedback controller would respond to the higher condenser water supply temperature and increase the tower airflow. At some load, the current set of operating chillers would not be sufficient to meet the load (i.e., maintain the chilled water supply set points) and an additional chiller would need to be brought online.

This example illustrated how different local-loop controllers might respond to load changes in order to maintain individual set points. Supervisory control might change these set points and modes of operation. At any given time, it is possible to meet the cooling needs with any number of different modes of operation and set points leading to the potential for control optimization to minimize an objective function.

The system depicted in Fig. 2 and described in the preceding paragraphs represents one of many different types of systems employed in commercial buildings. Medium-sized commercial buildings often employ multiple direct expansion (DX) cooling systems where refrigerant flows between each AHU and an outdoor condensing unit that employs variable capacity compressors. The compressor capacity is typically controlled to maintain a supply air temperature set point, which is still available as a supervisory control variable. However, the other condensing unit controls (e.g., condensing fans, expansion valve)

are typically prepackaged with the unit and not available to the EMCS. For smaller commercial buildings, rooftop units (RTUs) are typically employed that contain a prepackaged AHU, refrigeration cycle, and controls. Each RTU directly cools the air in a portion of the building in response to an individual thermostat. The capacity control is typically on/off staging of the compressor and constant volume air flow is mostly commonly employed. In this case, the only free supervisory control variables are the thermostat set points. In general, the degrees of freedom for supervisory control decrease in going from chilled water cooling plants to DX system to RTUs. In addition, the utility rate incentives for taking advantage of thermal storage and advanced controls are greater for large commercial building applications.

Optimal Supervisory Control

In commercial buildings, it is common to have electric utility rates that have energy and demand charges that vary with time of use. The different rate periods can often include on-peak, off-peak, and mid-peak periods. For this type of rate structure, the time horizon necessary to truly minimize operating costs extends over the entire month. In order to better understand the control issues, consider the general optimal control problem for minimizing monthly electrical utility charges associated with operating an all-electric cooling system in the presence of time-of-use and demand charges. The dynamic optimization involves minimizing

$$J = \sum_{p=1}^{\text{rate periods}} J_p + R_{d,a} \max [P_k]_{k=1 \text{ to } N_{\text{month}}}$$

with respect to a trajectory of controls $\vec{u}_k, k = 1 \text{ to } N_{\text{month}}$, $\vec{M}_k, k = 1 \text{ to } N_{\text{month}}$ where

$$J_p = R_{e,p} \sum_{j=1}^{N_p} P_{p,j} \Delta t + R_{d,p} \max [P_{p,j}]_{j=1 \text{ to } N_p}$$

with the optimization subject to the following general constraints

$$\begin{aligned} P_k &= P(\vec{f}_k, \vec{u}_k, \vec{M}_k) \\ \vec{x}_k &= x(\vec{x}_{k-1}, \vec{f}_k, \vec{u}_k, \vec{M}_k) \\ \vec{u}_{k,\min} &\leq \vec{u}_k \leq \vec{u}_{k,\max} \\ \mathbf{x}_{k,\min} &\leq \mathbf{x}_k \leq \mathbf{x}_{k,\max} \\ \vec{y}_k(\vec{f}_k, \vec{u}_k, \vec{M}_k) &\leq \vec{y}_{k,\max}(\vec{f}_k, \vec{u}_k, \vec{M}_k) \end{aligned}$$

where J is the monthly electrical cost (\$), the subscript p denotes that a quantity is limited to a particular type of rate period p (e.g., on-peak, off-peak, mid-peak), $R_{d,p}$ is an anytime demand charge (\$/kW) that is applied to the maximum power consumption occurring over the month P_k is average building power (kW) for stage k within the month, N_{month} is the number of stages in the month, $R_{e,p}$ is the unit cost of electrical energy (\$/kWh) for rate period type p , Δt is the length of the stage (h), N_p is the number of stages within rate period type p in the month, $R_{d,p}$ is a rate period specific demand charge (\$/kW) that is applied to the maximum power consumption occurring during the month within rate period p , $\mathbf{f}_k$ is a vector of uncontrolled inputs that affect building power consumption (e.g., weather, internal gains), $\vec{u}_k$ is a vector of continuous supervisory control variables (e.g., supply air temperature set point), $\mathbf{M}_k$ is a vector of discrete supervisory control variables (chiller on/off controls), $\mathbf{x}_k$ is a vector of state variables, $\mathbf{y}_k$ is a vector of outputs, and subscripts min and max denote minimum and maximum allowable values.

The state variables could characterize the state of a storage device such as a chilled water or ice storage tank. In this case, the states would be constrained between limits associated with the device's practical storage potential. When variations in zone temperature set points are considered within an optimization, then state variables associated with the distributed nature of energy storage within the building structure are important to consider. The outputs are additional quantities of interest, such as equipment cooling capacities, occupant comfort conditions, etc., that often need to be constrained. In order to

implement a model-based predictive control scheme, it would be necessary to have models for the building power, state variables, and outputs in terms of the control and uncontrolled variables. The uncontrolled variables would generally include weather (temperature, humidity, solar radiation) and internal gains due to lights and occupants, etc., that would need to be forecasted over a prediction horizon.

It is not feasible to solve this type of monthly optimization problem for buildings for a variety of reasons, including that forecasting of uncontrolled inputs beyond a day is unreliable. Also, it is very costly to develop the models necessary to implement a model-based control approach of this scale for a particular building. However, it is instructive to consider some special cases that have led to some practical control approaches. First of all, consider the problem of optimizing only the cooling plant supervisory control variables when energy storage effects are not important. This is typically the case for typical systems that do not include ice or chilled water storage. For this scenario, the future does not matter and the problem can be reformulated as a static optimization problem, such that for each stage k the goal is to minimize the building power consumption, $J = P_k$, with respect to the current supervisory control variables, $\vec{u}_k$ and $\mathbf{M}_k$, and subject to constraints. ASHRAE (2011) presents a number of heuristic approaches for adjusting supervisory control variables that have been developed through consideration of this type of optimization problem. This includes algorithms for adjusting cooling tower fan settings, chilled water supply air set points, and chiller sequencing and loading.

Other heuristic approaches have been developed (e.g., Braun 2007; ASHRAE 2011) for controlling the charging and discharging of ice or chilled water storage that were derived from a daily optimization formulation. For the case of real-time pricing of energy, heuristic charging and discharging strategies were derived from minimizing a daily cost function

$$J_{\text{day}} = \sum_{k=1}^{N_{\text{day}}} R_{e,k} P_k \Delta t$$

with respect to a trajectory of charging and discharging rates, subject to a constraint of equal beginning and ending storage states along with other constraints previously described. For the case of typical time-of-use (e.g., on-peak, off-peak) or real-time pricing energy charges with demand charges, heuristic strategies have been developed based on the same form of the daily cost function above with an added demand cost constraint $R_{d,k}P_k \leq TDC$ where TDC is a target demand cost that is set heuristically at the beginning of each billing period and updated at each stage as $TDC_{k+1} = \max(TDC_k, R_{d,k}P_k)$. The heuristic storage control strategies can be readily combined with heuristic strategies for the cooling plant components.

There has been a lot of interest in developing practical methods for dynamic control of zone temperature set points within the bounds of comfort in order to minimize the utility costs. However, this is a very difficult problem and so this remains in the research realm for the time being with limited commercial success.

Summary and Future Directions

Although there is great opportunity for reducing energy use and operating costs in buildings through optimal supervisory control, it is rarely implemented in practice because of high costs associated with engineering site-specific solutions. Current efforts are underway to develop scalable approaches that utilize general methods for configuring and learning models needed to implement model-based predictive control (MPC). The current thinking is that solutions for optimal supervisory control will be implemented in the cloud and overlay on existing building automation systems (BMS) through the use of universal middleware. This will reduce the cost of implementation compared to programming within existing BMS. There is also a need to reduce the cost of the additional sensors needed to implement MPC. One approach involves the use of virtual sensors that employ models with low-cost sensor inputs to provide

higher value information that would normally require expensive sensors to obtain.

Abstract

This entry provides an overview of building energy management systems (BEMS). It includes a description of the communication and control architectures typically used for energy management, definition of the optimal supervisory control problem, and a description

of current and future developments in optimal energy management.

Keywords

Building energy management · HVAC · Indoor climate control · Model predictive control · Inverse modeling · Predictive control · Optimization

Introduction

A building automation system (BAS) enables building operators to manage the indoor environment control system, along with fire and safety system and other auxiliary functions such as audio-visual systems in a building. The phrase building energy management system (BEMS) is sometimes used interchangeably with BAS, though energy management is only one aspect of a building's control system. Indoor environment control, which includes lighting and heating, ventilation, and air conditioning (HVAC), has a strong impact on energy use, and this may explain the meshing of the two terms. BEMS are typically used in large commercial buildings, though in recent times there is a trend toward smaller commercial buildings.

The number of possible types and configurations of HVAC systems in large buildings is enormous. In this section we will limit our discussion to single duct variable air volume (VAV), chilled water-based HVAC systems. Figure 1 shows a schematic of such a system. Constant air volume systems, in which the volume of air supplied to the building interior is constant over time, are gradually being phased out. The system shown is a single duct system, since the conditioned air is supplied to the zones through a single duct. Some buildings employ a dual duct system, in which outdoor air (OA) is supplied through a separate, dedicated OA duct. The system shown in the figure is a hydronic system since it uses water to transfer energy: chilled water produced in a chiller is supplied to one or more air handling units (AHUs) that cools and dehumidifies the air supplied to the interior of the building. Chilled

water-based systems are common in large buildings and even in some medium-sized buildings if they are part of a campus. In case of a campus, chilled water is produced in a chiller plant with multiple chillers. In cold and dry climates that do not require cooling and dehumidification, there is no cooling/dehumidification coil in the AHUs. Only heating coils are used, which may use heating hot water (HHW) or electric heating elements. Many buildings use packaged rooftop units (RTUs) that use a vapor compression refrigeration cycle to directly cool and dehumidify air. These systems are referred to as “DX” (Direct eXpansion) systems. DX systems are common in small and medium buildings that typically do not have BEMS.

Control Algorithms in Current BEMS

There are many BEMS vendors, such as Siemens, Johnson Controls, and Automated Logic. Almost all of these BEMS vendors also offer their HVAC equipment and controller hardware. The larger vendors offer their BEMS not simply as products but also solutions that can integrate HVAC equipment from other manufacturers. The BEMS from smaller vendors are usually used to integrate HVAC equipment from the same vendor.

At present, commercially available BEMS are mostly used to perform set point tracking control. The set points are specified by human operators through a user interface. The default values of these set points are usually chosen during building commissioning. Some of these set points are informed by decades of engineering practice and field studies. For instance, the conditioned air temperature (downstream of the cooling coil) is frequently chosen to be 55°F in hot humid climates (Williams 2013).

Even the simplest set point control loops are hybrid controllers, employing a mix of logic loops and PI controllers. For example, a commonly used zone VAV box control algorithm is the so-called single maximum control. Depending on the current temperature of the zone and its past history, the controller switches to one of the three modes: cooling, heating, and deadband. In each mode, there is a distinct set point for the zone temperature, and a PI controller is used

Building Energy

Management System,

Fig. 1 A hydronic HVAC system with an air handling unit (AHU) and multiple zones. A central chiller plant supplies chilled water (CHW) to multiple buildings

to manipulate the flow rate and the amount of reheating (except in the cooling mode in which reheating is turned off) to maintain that set point. These set point tracking control algorithms typically come prepackaged in BEMS, and modifications to their programming are performed during installation and commissioning. A programming interface is offered as part of the BEMS that allows automatic changes to the set points. The degree of flexibility of these programming interfaces is typically limited, so usually only simple rule-based logics can be implemented. For instance, the Siemens offers a programming interface using a proprietary language called *ppc1*, which is reminiscent of BASIC, with features such as GOTO statements that are deprecated in modern programming languages.

Communication in BEMS

There are multiple levels of communication among devices and sub-networks in a BEMS. A simple classification employs three layers: floor level network layer, management layer, and enterprise layer. BACnet is a communication protocol that runs on top of other existing electrical standards like RS-485 (serial communication), Ethernet, and MS/TP (Master slave/token passing). LonWorks was engineered to be both a data protocol and an electrical standard for digital communications. In the USA, BACnet is more

widely used compared to Modbus and LON. In modern buildings, “BACnet/IP over Ethernet” is probably the most relevant. That essentially means that the BEMS uses BACnet/IP protocol for communication among devices and BACnet packets are carried over Ethernet cables.

Interoperability is still an issue in BEMS even though BACnet was devised to resolve interoperability. A reason for this issue is that BACnet is a standard and not all vendors implement it the same way. To ensure the quality of BACnet implementation, one can apply for a BTL license, but most vendors do not. In recent years the NiagaraTM framework has provided a way to integrate multitude of devices from multiple manufacturers using diverse protocols.

Optimization-Based Control of Building Energy Systems

Opportunities

There is a large untapped opportunity to improve energy efficiency and indoor climate through advanced decision-making. This opportunity comes from gap between what the current BEMS are capable of and what they are being used for. Modern buildings equipped with BEMS typically have sufficient actuation capabilities at many levels (chillers, AHUs, and zone VAV

boxes) that can be controlled to deliver high performance in terms of energy efficiency and indoor climate. Against this possibility, the reality at present is that BEMS are used to maintain constant set points which are designed based on steady-state considerations. Thus, the simplest way to improve HVAC operational performance is to change the set points in real time by solving an optimization problem that takes into account the difference between the design conditions and actual conditions. Lower-level control algorithms that BEMS are already equipped with can then be tasked with maintaining these set points. This optimization problem has to be revisited periodically as new information – measurements and forecasts – becomes available. For this reason, there is an emerging consensus that model predictive control (MPC) – that repeatedly solves an optimization problem posed over a receding horizon – is appropriate for achieving high performance from existing BEMS. Another option is a model-free approach such as reinforcement learning, though little exploration has been performed into that frontier.

As in any control systems, sensing and actuation play as big a role as control algorithms. The control problem – whether one employs MPC or some other approach – can be made easier by adding more sensing and actuation. Additional actuation is quite expensive since that requires changing the building's physical structure. Adding sensors to a BEMS after it has been installed and commissioned is far more expensive than the cost of the sensors themselves due to the cost of integration and testing. Still, adding sensing is far less expensive than adding actuators. Adding advanced decision-making is perhaps the least expensive, especially if the computations are performed in the cloud, while the BEMS serves only to provide the sensor data and execute the decisions computed by the cloud-based algorithm through the building's actuators. This requires a middleware. BACnet, for instance, allows multiple commands to be sent to a controller board with different priorities, and the equipment controller implements the one with the highest priority. This mechanism can be

used by the middleware to overwrite the default control commands computed by the BAS and replace them by the commands from the cloud-based algorithm.

We next discuss some of the opportunities of achieving high-performance building operation using MPC and the challenges therein. Although the right metric for performance will vary from one building to another depending on the preference of the building owner, operator, and its occupants, it is common in the research literature to take energy use (or energy cost) as the objective function to minimize, while indoor climate requirements are posed as constraints. The key energy consumers are the chillers that produce chilled water, reheat coils, and supply air fans in air handling units (AHUs) and finally reheat coils in zone-level VAV boxes (see Fig. 1). The control problem therefore has to consider decisions for these equipment and the downstream effect of these decisions on the indoor climate. The energy consumed by pumps for chilled and hot water are ignored here.

“Air-Side” Optimal Control

In the so-called air-side optimization problem, the control commands are set points of air handling units and perhaps zone-level VAV boxes. Chiller operation is outside the purview of the decision-making problem and will be discussed in section “[The “Water-Side” Optimal Control](#)”.

The optimization problem underlying an MPC controller will seek to minimize some objective function subject to the dynamic constraints and actuator limits. In a discrete-time setting, at time index k , the MPC controller computes the decisions $u_k, u_{k+1}, \dots, u_{k+N-1}$ over a planning horizon $\mathcal{K}_k = \{k, k+1, \dots, k+N-1\}$ of length N by solving an optimization problem of finite (N -length) horizon. The planning horizon depends on many factors. If the objective is to minimize energy cost, and monthly peak demand plays an important role in the energy cost, the planning horizon needs to span months. A day-long planning horizon seems to be the shortest possible while keeping the problem practically relevant.

The Single-Zone Case

We describe the problem in detail for a building in which an AHU is used to maintain the climate of one space, which we refer to as a “single-zone” building. In such a building, shown in Fig. 2, only four variables can be independently varied, which form the control command u : (i) $\dot{m}^{SA}$, the flow rate (kg/s) of *supply air*, (ii) r^{OA} , the *outdoor air ratio*, i.e., the ratio of outdoor air to supply air flow rates, $r^{OA} := \dot{m}^{OA} / (\dot{m}^{OA} + \dot{m}^{RA}) \in [0, 1]$, (iii) T^{CA} , the temperature of *conditioned air*, and (iv) q^{rh} , the rate of reheating (kW). Thus, $u_t = [\dot{m}^{SA}, r^{OA}, T^{CA}, q^{rh}]_t^T \in \mathbb{R}^4$. Each of these four control commands are in fact set points of lower-level control loops that are common in existing building control systems.

There are many choices of control that can lead to similar indoor climate but distinct energy consumption. A small T^{CA} with small $\dot{m}^{SA}$ can deliver the same “cooling” as a slightly larger T^{CA} and larger $\dot{m}^{SA}$. While lower $\dot{m}^{SA}$ uses less energy consumption, lower T^{CA} causes more energy consumption since it removes more moisture, which requires removing the large latent heat of evaporation. It is important to emphasize that the conditioned air temperature and humidity T^{CA}, W^{CA} cannot be decided independently, only T^{CA} is a part of the control command since it can be maintained by a chilled water control loop. The humidity of the conditioned air is indirectly decided by T^{CA} due to the dynamics

of the cooling coil. The relationship is highly complex and challenging to model for real-time optimization (Raman et al. 2019).

The relationship between the control command u and the disturbance d to indoor climate variables is best expressed as process (dynamic) models. They form the equality constraints in the optimization. Inequality constraints come from actuator limits and bounds on climate variables (state constraints). Apart from the dynamic constraints, there are two other types of constraints. The first set of constraints comes from thermal comfort and indoor air quality considerations. The second set comes from actuator limits.

For the purpose of exposition, we use the total HVAC energy (over a time interval N) as the objective function in the MPC optimizer: $J = E_{tot} = \sum_{t=k}^{k+N-1} (p_t^{cd} + p_t^{rh} + p_t^{fan}) \Delta t = \sum_{t \in \mathcal{T}_k} p_t^{tot} \Delta t$, though other choices are possible, such as the monthly energy cost that depends on total energy use and sometimes on a combination of energy use and peak demand during the month. In summary, the optimization problem within the MPC controller at time k is:

$$\begin{aligned} u_k^* &= \arg \min_{u_k, x_k} J(u_k, x_k, \hat{d}_k), \text{ s. t. } x_{k+1} \\ &= f(x_k, u_k, \hat{d}_k), x_k \in \mathcal{X}_k, x_k \in \mathcal{U}_k \end{aligned} \quad (1)$$

where $u_k := (u_k, \dots, u_{k+N-1})$ and $x_k := (x_k, \dots, x_{k+N-1})$ are the inputs and states, and

Building Energy Management System, Fig. 2 A single zone VAV HVAC system

$\hat{\mathbf{d}}_k = (\hat{d}_k, \dots, \hat{d}_{k+N-1})$, in which $\hat{d}$ is prediction of disturbance d , and $\mathcal{X}_k, \mathcal{U}_k$ are constraint sets for states and inputs.

Climate controllers currently used in buildings do not optimize; they err on the side of maintaining indoor climate since that is far more important than the energy bill (Tom 2008). Typically, T^{CA} is maintained by a PID loop at a set point that is decided based on decades of engineering experience. For instance, most hot and humid climates T^{CA} is set to 55°F (Williams 2013). The flow rate $\dot{m}^{\text{SA}}$ and reheating rate q^{rh} are decided by feedback controllers to ensure space temperature is within predetermined bounds; the bounds are again decided based on decades of research on human comfort (Baughman and Arens 1996; American Society of Heating, Refrigerating and Air-Conditioning Engineers 2010). Finally, the outdoor air ventilation is usually maintained at a set point based on design occupancy, which fixes the fourth component of $\mathbf{u}$, namely, r^{OA} .

The disturbance and its predictions play a crucial role in predictive control. The disturbance d consists of five components: (i) weather variables: solar heat gain η^{sun} , OA temperature T^{OA} , and OA humidity W^{OA} , and (ii) internal signals: sensible heat gain q^{int} (mostly from occupants and their actions, such as use of computers and lights), internal moisture generation rate $\dot{m}_{\text{H}_2\text{O}}$ (from occupants' bodies, decorative plants, coffee machines, etc.), and the number of occupants o . At every instant k , the optimizer needs predictions of all the exogenous signals for the planning horizon. Except for weather-related variables, obtaining forecasts of the remaining disturbance signals is a highly challenging problem.

Multi-zone Case

In most buildings an AHU is used to deliver air to multiple zones (see Fig. 1). The problem described above can be expanded to the multiple-zone case in a straightforward manner. The state dynamics will involve the states of thermal dynamics from each zone, and the control command will now include not simple AHU-level variables but also the set points for each of the VAVs. The problem is considerably more

challenging and not simply due to the higher computational complexity caused by the higher state dimension. Additional challenges come from the higher degree of uncertainty in models.

The “Water-Side” Optimal Control

The so-called water-side control problem is to make decisions about the chiller and cooling towers. Most chillers at present are run by constant-speed motors, so the key decision is turn a chiller in a bank of chillers either on or off. Even in constant speed chillers, the load on the chiller can be changed by actuating the inlet guide vanes. In some chiller plants, the supply water temperature can be manipulated and that becomes another decision variable. The water side problem is applicable only with buildings with chillers, which is more common in a campus or district setting (Patel et al. 2018).

Challenges

There are many challenges in successfully applying MPC to HVAC systems. One is the need for an accurate and yet computation-friendly dynamic model. Although there is a long history of modeling HVAC systems and equipment, there are still unresolved issues. The underlying physical processes involve conductive, convective, and radiative heat transfer as well as mixing and transport of several species such as moisture and CO_2 . Thus, first principles-based models can be arbitrarily complex. A popular class of models for modeling temperature evolution in a building is based on the resistance-capacitance networks, whose parameters are fitted to measured temperature data. There is a large unknown disturbance that comes from heat gains from occupants and their activities that makes system identification challenging (Coffman and Barooah 2018). Moreover, these models ignore humidity; work on identification of models that include both temperature and humidity is rare. Constructing control-oriented models for HVAC equipment, such as the cooling and dehumidification coil, is more challenging (Raman et al. 2019).

Another challenge for MPC-type control is the need for prediction of the disturbance signal over the planning horizon. Recall that there are many components in the disturbance signal, and while weather-related disturbances can be reasonably forecasted, signals such as number of occupants and the moisture generation are difficult to predict.

Yet another challenge is addressing the high computational complexity due to the large number of decision variables, especially where there are a large number of zones and the planning horizon is long.

Building-Specific Requirements

There are many types of buildings, and all have their own unique requirements on indoor climate which spill over to the constraints on the climate control system, MPC or not. Healthcare-related facilities in particular require special considerations and have distinct environmental constraints. The HVAC system described in detail in section “[“Air-Side” Optimal Control](#)” is a hydronic (chilled water) system. The details of the control problem will differ in case of a DX cooling system, which are used widely in packaged rooftop units used in small commercial buildings.

The air-side control problem discussed in section “[Optimization-Based Control of Building Energy Systems](#)” involved continuously variable actuators and set points, and the optimization becomes a nonlinear program (NLP). However, in case of a DX system, the decision variables may be integer valued if compressor stages need to be decided. In fact, many large HVAC equipment are ultimately on-off, such as compressors in chilled water plants, cooling towers with constant speed fans, etc. The optimization problem therefore becomes a mixed integer nonlinear programs (MINLP), which are considerably more challenging to solve than NLPs. Advances in solving MINLPs will thus benefit adoption of MPC in buildings.

Two other applications in which optimal control of BEMS can play an important role are demand side services and management of on-site renewable energy sources. More generally, in any building that moves away from the traditional

role of being purely a consumer of energy that is supplied by someone else (power grid, gas grid, etc.) to one of a *prosumer* that uses on-site generation, and perhaps energy storage, can benefit significantly from more intelligent real-time decision-making than the currently available rule-based control algorithms of existing BEMS.

Summary and Future Directions

BEMS augmented with advanced decision-making algorithms can improve both indoor climate and reduce energy use. In addition, they can help operate buildings with on-site generation and storage resources. There are many challenges in achieving this vision. Control-oriented models learned automatically from data, prediction of exogenous disturbances, and optimization algorithms all need advances. Another option is model-free (learning-based) control. No matter the approach, the resulting methods need to be inexpensive to deploy and maintain, which is challenging due to differences among buildings and changes that occur in a building over time. The systems and control community is well positioned to address many of these challenges.

Building Fault Detection and Diagnostics

Jin Wen¹, Yimin Chen², and Adam Regnier³

¹Department of Civil, Architectural, and Environmental Engineering, Drexel University, Philadelphia, PA, USA

²Building Technology and Urban Systems Division, Lawrence Berkeley National Laboratory, Berkeley, CA, USA

³Kinetic Buildings, Philadelphia, PA, USA

Abstract

Malfunctioning control, operation, and building equipment, such as unstable control loop, biased sensor, and stuck outdoor air damper, are considered as the top cause for “deficient” building systems. In this article, types of faults that are commonly observed in a building system are introduced firstly. Literature-reported fault detection and diagnosis methods for building systems are then briefly summarized, which is followed by a discussion on the technical challenges in building system fault detection and diagnosis areas. Other topics, such as impacts that a fault could cause to a building, how to evaluate a fault detection and diagnosis method, and issues related to

implementing a fault testing, are reviewed next. Future directions in this area are presented at the end of this article.

Keywords

FDD · Fault impact · FDD evaluation · FDD challenges

Introduction

Malfunctioning control, operation, and building equipment, such as unstable control loop, biased sensor, and stuck outdoor air damper, are considered as the top cause for “deficient” building systems. These dramatically increase the building energy consumption (estimated that between 0.35 and 17 quads of additional energy consumption caused by key faults at a national level (Roth et al. 2004), and significantly impact the health/productivity of occupants. Field studies have shown that an energy saving of 5–30% and improved indoor air quality can be achieved by simply applying automated fault detection and diagnosis (AFDD) followed by corrections even if these are not done in real time (Katipamula and Brambley 2005a).

In Haves (1999), fault detection is defined as “determination that the operation of the building is incorrect or unacceptable in some respect” and fault diagnosis is defined as “identification or localization of the cause of faulty operation.” In order to perform fault detection, a “correct” or “acceptable” operation and system status typically needs to be established first. This status is referred to as “baseline” and/or “fault free” status, although a true “fault-free” status does not really exist in real building systems. For example, a common economizer fault is that an outdoor air damper is stuck at a fixed position. To detect this fault, the “correct” outdoor air damper position, i.e., the baseline or fault-free status, needs to be established first. A fault detection could be performed at a component (such as a damper) level, subsystem (such as an economizer) level, system (such as an air handling unit) level, or whole building level. The output of a fault detection is an alarm or report that indicates the monitored

object (component, subsystem, system, or whole building) is “faulty,” i.e., performs abnormally from its baseline/fault-free status.

Compared to fault detection, fault diagnosis is much more difficult because more knowledge, information, and analysis are needed to isolate the root causes that impact the system performance. For example, a fault detection process might detect an air handling unit to be “faulty.” However, what exactly causes this system to be faulty needs to be identified in a fault diagnosis process.

It is noticed that existing literature does not clearly separate the concepts of AFDD and fault detection and diagnosis (FDD). A reason for this could be due to the challenge to define the concept of “automated,” as many AFDD strategies may still engage some manual efforts. Hence these two concepts are not strictly separated in this article.

Types of Faults

There are many ways to categorize faults in a building. Faults can be categorized by the location of the malfunctioned (faulty) component. Such as envelope fault, air handling unit fault, chiller fault, etc. Faults can also be categorized by the types of component that a fault affects, such as hardware fault and software fault. Hardware faults can further be divided into sensor fault, controlled device (damper, valve, etc.) fault, and equipment (fan and coil, etc.) fault. Software faults can further be divided into operator fault (i.e., forgot to remove a software override command) and control fault (unstable control, sluggish control, wrongly programmed control strategy, etc.). Faults can be categorized by how a fault occurs and progresses, such as abrupt faults (occur suddenly and do not progress further) and degrading faults (occur slowly and progress overtime). Examples of abrupt faults include damper or valve stuck fault, fan failure fault, software override fault, etc. Examples of degrading faults include sensor bias fault, in which the bias often changes over time, coil fouling fault, and fan efficiency degradation

fault. Depending on how many subsystem a fault impacts, faults can be categorized as component (or local) faults or whole building faults. The latter refers to those faults that occur in one subsystem but affect more than one subsystem. For example, a chilled water supply temperature sensor bias fault affects operation of both the chiller and the air handling units that the chiller serves.

FDD Methods

Many methods have been developed for component level and whole building level AFDD for building systems. In Katipamula and Brambley (2005a, b) and Kim and Katipamula (2018), Katipamula, Brambley, and Kim provided a comprehensive classification for methods used for HVAC system AFDD as shown in Fig. 1.

These methods have been reported to be used for fault detection alone without isolating the root cause or for a combination of both fault detection and fault isolation.

Some new studies that are not discussed in Katipamula and Brambley (2005a, b) and Kim and Katipamula (2018) have reported successful application of Bayesian network (BN) for fault diagnosis, including its application for chiller fault diagnosis (Zhao et al. 2013), air handling unit fault diagnosis (Zhao et al. 2015), and whole building fault diagnosis. The use of Bayesian networks (BN) seeks to combine the aspects of both rule-based and data-driven approaches with many of the benefits of a probabilistic data-driven approach combined with the benefits of a rule-based approach in a single algorithm.

Technical Challenges

Many technical challenges still exist when developing AFDD tools for building systems, which often make reducing the product cost a difficulty:

1. Challenge of limited measurements and poor measurement quality: Measurements used for

Building Fault Detection and Diagnostics, Fig. 1 Classification scheme for FDD methods (Katipamula and Brambley 2005a)

- building AFDD tools are most commonly obtained from a building automation system (BAS). Yet the sensor system in a BAS is designed for building control purpose, not for AFDD purpose. There is a lack of redundant measurements to increase measurement reliability. As a result, sensor faults have strong impact on overall AFDD accuracy and false alarm rate.
2. Challenge of building measurement taxonomy: A lack of standard measurement and data taxonomy has been a well-recognized challenge for building AFDD tools. Engineers and researchers often have to spend significant time to understand the physical meaning of point (measurement) names and their hierarchy and to correlate these measurements with AFDD strategies.
 3. Challenge of qualitative and quantitative model-based methods: Developing and calibrating physics-based models to reach an accuracy level that is sufficient for building AFDD, especially for whole building AFDD, remains to be challenging and requires expensive manual inputs. At the same time, qualitative and quantitatively model-based tools often suffer from low scalability when being applied for different buildings, due to the needs to customize physics-based models, rules, and thresholds
 4. Challenge of process history-based method: Process history-based methods have good scalability and low implementation cost. However, these methods rely on data. Hence data quality strongly affects the performance of these AFDD tools. As mentioned in Challenge 1, building data quality is much worse than those from other applications, such as process line. In a real building, missing data and a lack of trended data are common, which further complicate the application of process history-based methods. Moreover, for whole building AFDD tools that need to utilize data from the entire building, which often has hundreds, if not thousands of data points, how to handle such an increased data dimensionality in a computationally efficient way, also referred to as the curse of the data dimensionality, is a challenge.
 5. Challenge of generating baseline data: For building systems, it is often challenging to differentiate weather and/or internal load triggered system operational changes from fault triggered abnormalities. Difficulties exist as to how to collect historical baseline data, and how to efficiently select among these collected historical baseline data, those baseline data that are under similar weather and internal load conditions as the current data from system operation. Notice that a real building sys-

tem is often impossible to be at a true “fault-free” status. How to define baseline status and how to define threshold (difference between fault-free and faulty statuses) are key challenges for building AFDD tools.

6. Challenge of fault diagnosis and multiple faults: Many methods have been reported for fault detection, i.e., identifying abnormalities. Yet there is a lack of studies that focus on locating and identifying root causes, especially for those faults that cause abnormalities in multiple subsystems/components, i.e., have coupled abnormalities. For example, if the supply air temperature sensor in an air handling unit has a positive bias, i.e., screen reading is higher than its real value, the real supply air temperature would be lower than its set point. Hence the abnormalities could include increased cooling coil valve, abnormal chilled water loop pressure/flow rate, and reduced downstream variable air volume unit damper positions. Moreover, in a real building system, it is common that multiple faults exist. How to isolate multiple faults (Li and Braun 2007) has been rarely reported in the open literature.
7. Challenge of FDD method evaluation: Literature-reported FDD methods are mostly developed and evaluated using simulated system data. This is due to the difficulties of obtaining and analyzing real building data. Implementing faults and obtaining data that contain fault impacts in real buildings are already challenging. Yet cleaning and analyzing building data to obtain “ground truth” is even more arduous since unexpected naturally occurring faults could exist in the system and cause abnormalities or complicate (sometimes even eliminate) the fault impacts expected from the artificially implemented faults.

Fault Impacts

A fault in building systems affect the building’s energy consumption, indoor environmental quality, and systems’ lifespan. Notice that not all fault impacts are adverse. For example, if the

outdoor damper is stuck at a 100% open position, higher-than-normal ventilation air will be brought into the building. Hence this fault might have a positive impact on the indoor environmental quality. Of course, meanwhile, excessive energy might need to be spent to condition this additional ventilation air. Hence this fault has an adverse impact on building energy consumption. Vice versa, there are faults that have an adverse impact on indoor environment yet might save energy. Overall speaking, there is very limited information in the literature relating to the overall energy impacts and other impacts of faults on HVAC systems. Impacts of undetected faults are a function of multiple factors, such as:

- How to define “fault-free” baseline operation
- The probability of the fault occurring
- The probability of the fault going undetected without an effective AFDD procedure in place

Kim and Katipamula (2018) provide a summary of studies that report on fault impacts.

FDD Method Evaluation

Many market-available AFDD tools and literature-reported AFDD methods have been developed. However, there is no standard method to evaluate these tools/products and to report their performance, such as the diagnostic accuracy and/or cost effectiveness. The following gaps exist when reporting an AFDD tool/method:

1. Whether the tool requires the installation of additional sensors that are not typically found in existing systems. The installation of additional expensive sensors, like BTU/flow meters on the coil piping or additional air flow stations, is often prohibitive in the widespread adoption of a proposed AFDD tool.
2. Whether the tool requires costly engineering effort to be implemented in the field. Common causes for such additional engineering hours include fault data generation/collection, strategy and fault threshold customization for each installation, and modeling of the physical systems/components.

3. Whether the strategy is effective at maintaining its accuracy through multiple operational modes and transient states typically experienced during a system's normal operation. Many strategies that have been demonstrated to be effective in specific operational conditions are not adaptive for other operating conditions.
4. False alarm rates are rarely reported in the literature. Yet this has been widely identified by the industry as a key factor delaying widespread commercial adoption of AFDD tools for building systems.
5. Whether the strategy is able to handle the typical real-world BAS data quality. Strategies that are only tested using simulated data might experience difficulties when applied to real buildings due to problems with typical BAS data (missing data, noise, sensor faults, sensor accuracy, etc.).
6. Whether the strategy can easily be applied in different buildings, i.e., scalability. Strategies that are developed for a specific building or a specific type of system might experience difficulties when applied to other buildings/systems.

Without a standardized evaluation method, it is very hard for building owners/operators and building service companies to select a proper AFDD strategy/product that suits their needs.

Several studies (such as in Yuill and Braun 2013) have reported on methodologies for comparing AFDD tools for some components such as rooftop unit (RTU). Currently, a standardized method of testing is being developed for RTU FDD methods at the American Society of Heating, Refrigerating, and Air-conditioning Engineers (SPC 207p). An ongoing project (Granderson 2018) being performed by the Lawrence Berkeley National Laboratory (LBNL) aims at developing more evaluation methodologies for other HVAC component AFDD.

Implementing Fault Testing

In order to collect data for AFDD method evaluation, faults often need to be artificially injected to

a real system. There are generally two methods to artificially implement a fault: via the BAS or via the hardware. For example, a damper stuck fault can be implemented via the hardware by disconnecting the motor from the existing BAS and connecting it with a constant input signal (e.g., by a voltage meter) to maintain the damper position. It can also be implemented via the BAS by software-overriding the control signal at a desired constant. However, when a fault is implemented via the BAS, collected BAS measurements need to be post-processed to imitate those from a real fault event. Using the same damper stuck example discussed above, if the fault is implemented by software-overriding the damper control signal, the real control signal generated from the control algorithm for outdoor air damper needs to be recorded and need to replace the software-overridden damper signal because if a real damper stuck fault occurs, the damper control signal would not be the constant of the stuck position. Understanding how a fault would affect the trended measurements is critical for a successful fault implementation. When implementing faults in a real building or real system, data need to be carefully and manually analyzed to identify the ground truth. In general, several scenarios could happen from the collected data: (1) no artificial fault is implemented but naturally occurring fault exist; (2) artificially implemented fault has caused system abnormality; (3) artificially implemented fault has not caused any measurable system abnormality under the weather and operation conditions tested; and (4) both artificially implemented fault and naturally occurring faults exist and have caused abnormality.

Limited data and test bed, such as that reported by Wen and Li 2012, exist in the open literature that can be used to test AFDD tools. The LBNL project mentioned above (Granderson 2018) is aiming at developing more data and test bed.

Summary and Future Directions

Faults in building systems strongly affect a building's energy consumption, indoor environment quality, and overall system lifespan. Many studies exist in the literature that focus

on AFDD method development for both HVAC component or whole building faults. Qualitative, quantitative, and process history-based methods have all been reported. However, many challenges have prevented a wide adoption of AFDD tools in the field. The primary drivers for growth of adoption of AFDD solutions include (1) reduction of implementation costs; (2) education of customers; and (3) industry standards, including standardized terminology and benchmarks or ratings that can be used for the evaluation of competing technologies. Innovations in machine learning and artificial intelligence have provided potential techniques to overcome these challenges. There is generally a lack of fault diagnosis method reported in the literature, especially for multiple simultaneous faults. Fault impact analysis, fault method evaluation, and real building fault testing are also lacking in the literature and need further development.

Building Lighting Systems

Sandipan Mishra

Department of Mechanical, Aerospace, and Nuclear Engineering, Rensselaer Polytechnic Institute, Troy, NY, USA

Abstract

Feedback control of lighting systems ranges from rule-driven on-off control to optimization based control algorithms. Simple lighting control algorithms use illumination and occupancy sensor measurements to dim lighting and harvest ambient lighting, whenever possible. For networks of lighting fixtures, illumination balancing algorithms use local information from sensors to achieve uniform lighting in a decentralized manner. Optimization-based algorithms are particularly useful for control of lighting fixtures with multi-spectral light sources. Such schemes are typically model based, i.e., they require knowledge of the light transport inside the illuminated space and rely on color quality indices and light source efficiencies to balance occupant comfort with energy consumption.

Keywords

Optimization-based control · Predictive control · Light transport · Distributed control · LED lighting

Introduction

Indoor illumination is a key component of a comfortable building interior and significantly affects health, productivity, mood, comfort, security, and safety of the occupants. In 2015, artificial indoor lighting in the residential and commercial sectors consumed nearly 404 billion kilowatt-hours (kWh) of electricity in the United States (Conti 2013). While traditional lighting systems were mainly designed to provide illumination alone, the new generation of lighting systems takes advantage of recent developments in solid state lighting and the advances in the state-of-the-art spectral and occupancy sensing technology to deliver functionality beyond just illumination. These lighting fixtures mix light from different light emitting diodes (LEDs) to create energy-efficient, high-quality, and healthy illumination. Lighting control systems use occupancy information and illumination measurements information to adjust LED intensities to produce comfortable illumination in an energy efficient way.

Although LEDs are more energy-efficient as compared to incandescent and fluorescent bulbs, feedback control of lights can enable further energy savings in two ways (1) occupancy-based lighting and (2) daylight harvesting. The former refers to the dimming of the light fixtures in unoccupied zones of the building, while the latter is based on harvesting ambient light from windows (or skylights) so that fixtures can be dimmed to save energy. Feedback control is particularly important for lighting systems because of unpredictable and time-varying nature of occupancy, naturally changing daylight conditions, and changes in light transport inside the illuminate space. In addition to energy savings, human comfort, mood, productivity, and health are also critical from a lighting standpoint. Most light control algorithms typically consider three lighting quality metrics: uniformity, brightness, and color quality. In general, lighting comfort depends on several parameters such as illumination, correlated color temperature (CCT), perception of color, and glare.

A schematic of a closed loop lighting control system is shown in Fig. 1. The “plant” is the indoor space being illuminated; the controlled inputs are the (multi- or single-channel) LED fixture commands; disturbances include the ambient daylight, while typical feedback is obtained

B

Building Lighting Systems, Fig. 1 Schematic of a typical lighting control system. (Figure taken from Imam et al. 2016)

from ambient illumination measurements or color sensor readings. Occupancy sensors are often used to detect the number and/or location of the occupants, and the color sensors measure the intensity and spectral content of the incident light. Occupancy information is used to determine the desired lighting for the space, while the color (or ambient brightness) measurements are used to maintain the desired illumination condition (y_d). The controller uses the lighting set-point values and the sensor measurements and generates the required input for each channel of the LED fixture(s) to achieve the control objective, which is based on a set of parameters determined by the building manager or user (e.g., energy cost, uniformity requirement, etc.). Performance metrics for the lighting system typically include energy consumption, uniformity, brightness, and color quality indices such as Color Rendering Index (CRI) or Color Quality Scale (CQS).

Light Transport Modeling

While high-fidelity ray tracing software such as Zemax may be used to directly simulate illumination of the indoor space, these models are not suitable for design of feedback control. We now present a brief description of the typical model for light transport in an indoor space used for designing feedback controllers.

Consider a space with n light fixtures, each of which contains p adjustable intensity channels (e.g., different color LEDs). Assume that the input to each fixture is represented as a vector, $u^i \in \mathbb{R}^p$, $i = 1, \dots, n$, and each entry in u^i is normalized to the range $[0, 1]$. If there are m locations of interest for the overall light field in the space, and there is a sensor with q channels of spectral sensing at each of these locations, then the output vector is a vector with qm elements, consisting of the different $y^j \in \mathbb{R}^q$, $j = 1, \dots, m$. The input-output model for this space can be given by:

$$y = Gu + w + v \quad (1)$$

where $y = [y^1, y^2, \dots, y^m]^T \in \mathbb{R}^{3m}$ is the output light measurement vector, $u = [u^1, u^2, \dots, u^n]^T \in \mathbb{R}^{pn}$ is the input light intensity control vector, $G \in \mathbb{R}^{3m \times pn}$ is the **Light Transport Matrix** (Foley et al. 1995) (LTM), $w \in \mathbb{R}^{3m}$ is the effect of ambient light on the sensors, and $v \in \mathbb{R}^{3m}$ is the measurement noise. The LTM is used to characterize the input-output relationship for the lighting system.

Feedback Control of Lighting

Lighting control methodologies can be broadly classified into three categories (1) logic-based controllers, (2) regulation-based controllers, and (3) optimization-based controllers. In logic-based methods, discrete logical statements and conditionals are used to determine the correct action for the lighting system in different situations based sensor measurements and a set of rules (Wen and Agogino 2010). Regulation-based control algorithms used feedback measurements to track predetermined reference value (Rubinstein 1984). Optimization-based algorithms are an alternative approach to controller design for closed loop lighting systems where the control problem is posed as an optimization problem and solved in real-time using optimization techniques (Afshari et al. 2014; Caicedo and Pandharipande 2016).

Optimization-based algorithms can be further classified into two sub-categories. In one-shot optimization algorithms, the control law is obtained by choosing the optimal solution at each time-step of the control loop. In iterative optimization algorithms, gradient-based methods are used to obtain the optimal direction for the evolution of the system at each time-step. The input for the next time-step is obtained by making an incremental change in the current input in the gradient direction. This process is repeated until the system converges to the global optimum of the cost function. While the one-shot optimization algorithms are deadbeat, they are typically more sensitive to noise and can significantly degrade in performance in the

presence of model uncertainty. We now describe five lighting control algorithms in greater detail.

Decentralized Integral Control

The simplest lighting control methodology that guarantees zero steady state error in the presence of sufficiently slowly varying disturbances is pure integral control:

$$u(k) = u(k-1) + \alpha (y_d(k-1) - y(k-1)) \quad (2)$$

where α is the controller gain, (y_d) is the desired, and (y) is the measured sensor measurements at k -th time-step. For decentralized implementation of this integral controller, the control law for i -th location is:

$$u_i(k) = u_i(k-1) + \alpha (y_d(k-1) - y_i(k-1)) \quad (3)$$

where α is a design parameter that controls the speed of convergence and $y_d(k-1)$ and $y_i(k-1)$ are, respectively, the desired and measured light levels at i -th location at the $(k-1)$ -th time-step. This control law is termed Decentralized Integral Controller (DIC).

Illumination Balancing Algorithm

For lighting systems with collocated light sources and sensors, cross-illumination between the different fixtures can cause nonuniform illumination if a simple DIC control law is used. In Koroglu and Passino (2014), Koroglu and Passino addressed this issue by proposing a distributed control algorithm called Illumination Balancing Algorithm (IBA), which uses the illumination levels of the neighboring fixtures to generate the control input for each fixture.

The control objective of IBA is Koroglu and Passino (2014) to track a desired light level while ensuring uniform illumination across all the zones of the work space, with communication among the light fixtures being restricted within a neighborhood. The work space is divided into pre-defined zones, where each zone consists of a monochromatic (white channel only) light source and a Light Dependent Resistor (LDR) is the light sensor. An arbitrary zone l is chosen as the

“leader.” This leader is the only fixture that has knowledge of the *desired* illumination level. For this fixture, illumination balancing and integral control are simultaneously used, as described in the first equation of (4). The rest of the zones only balance their illumination levels with their pre-defined neighbors (described in the second equation of (4)). Without explicitly knowing the target illumination value, these zones eventually track the desired illumination level by following the leader zone l . The control law is given by:

$$\begin{aligned} u_l(k) &= u_l(k-1) + \alpha e_l(k-1) \\ &\quad - \sum_{j \in N(l)} \gamma (y_l(k-1) - y_j(k-1)) \\ u_i(k) &= u_i(k-1) \\ &\quad - \sum_{j \in N(i)} \gamma (y_i(k-1) - y_j(k-1)) \quad i \neq l. \end{aligned} \quad (4)$$

where $N(i)$ represents the set of neighboring zones adjacent to the i -th zone and γ is a scaling factor that determines the stability margin and convergence speed. We refer the reader to Koroglu and Passino (2014) for a detailed development.

Daylight and Occupancy Adaptive Lighting Control

Unlike the distributed approach taken in IBA, a centralized control approach can be adopted for lighting control, as in Caicedo et al. (2010). In this algorithm, a centralized control law was designed to optimize power efficiency through daylight harvesting and occupancy adaptation. The objective was to minimize the total power consumption of the system while ensuring a variable level of minimum illuminance at each sensor and keeping the input intensities of the neighboring light fixtures close together. The desired minimum level of illuminance in a zone depends on its occupancy.

Light fixtures typically use pulse width modulation (PWM) for dimming, for which the power consumption by each light channel is proportional to its input intensity. Based on this fact,

the total power consumption of the system as the summation of the input intensities of the light fixtures at any given time k is $\sum_{i=1}^n \frac{u_i(k)}{\eta_i}$, where η_i is the efficiency of the i th fixture (channel). The overall optimization problem can be formulated as follows:

$$\Delta \mathbf{u}(k) = \underset{\Delta \mathbf{u}}{\operatorname{argmin}} \sum_{i=1}^n \frac{u_i(k-1) + \Delta u_i(k)}{\eta_i} \quad (5)$$

subject to the following constraints:

$$\begin{aligned} \mathbf{G} \Delta \mathbf{u}(k) &\geq \mathbf{y}_d^x(k) - \mathbf{y}(k-1), \\ -\Delta \mathbf{u}(k-1) &\leq \Delta \mathbf{u}(k) \leq \mathbf{1} - \Delta \mathbf{u}(k-1), \\ |\Delta u_i(k) - \Delta u_j(k)| &\leq \delta u - \Delta u_i(k-1) \\ &\quad + \Delta u_j(k-1), \end{aligned}$$

$$\text{where } i=1, \dots, n \text{ and } \forall j \in N(i)$$

where $\Delta \mathbf{u}(k) = [\Delta u_1(k), \dots, \Delta u_n(k)]^T$ is the incremental step vector for input intensity, $\mathbf{y}(k-1)$ is the sensor measurement, $\mathbf{y}_d^x(k)$ is the desired illuminance based on the occupancy state, x represents the occupancy state (0 and 1 mean unoccupied and occupied, respectively), δu is maximum allowed increment, $N(i)$ is the set of neighboring fixtures for the i -th fixture, and $\mathbf{G} \in \mathbb{R}^{qm \times pn}$ is the LTM.

The optimization problem with the (linear) objective function and constraints in (5) is solved using the interior point method in an iterative approach (Caicedo et al. 2010). The control update for time k is:

$$\mathbf{u}(k) = \mathbf{u}(k-1) + \alpha \Delta \mathbf{u}(k) \quad (6)$$

At each time instant k , the centralized controller solves the linear optimization problem in (5) to obtain the incremental step vector for the input intensity $\Delta \mathbf{u}(k)$ and uses the update equation (6) to obtain the complete input intensity vector $\mathbf{u}(k)$ for the next time-step. This algorithm assumes co-located light fixtures and sensors and an occupancy sensor for each zone. The design parameter α determines the speed of adaptation and can be adjusted to achieve smoother transition of the intensity levels.

Spectral Optimization for Polychromatic Lighting

The control strategies discussed in the previous sections were designed for single-color lighting systems. Aldrich et al. (2010) studied the problem of controlling color-tunable LED fixtures, which can generate a wide range of colors. As in Caicedo et al. (2010), the control design is posed as a constrained optimization problem. The objective is to minimize energy consumption or maximize the color rendering index (CRI) for a given user-specified color temperature (T_d).

The piecewise cost function includes three terms, as shown in (7), namely, (1) the 2-norm of the difference between the desired and measured color temperatures (T_d and T), (2) a nonlinear term ($\Delta uv(T)$) that quantifies the distance between the generated color and the black body curve, (The black body curve characterizes the set of all color points of the light radiated from a black body at different temperatures.) and (3) an additional term that is either the normalized power consumption or the normalized CRI of the generated light.

$$\min_u \quad \mathbf{J}(u) = \begin{cases} \left(\frac{T_d - T(u)}{T_d} \right)^2 + \alpha_1 \Delta uv(T(u))^2 + \alpha_2 \left(\frac{\Gamma_E u}{P_t} \right)^2, & \text{Power minimization} \\ \left(\frac{T_d - T(u)}{T_d} \right)^2 + \alpha_1 \Delta uv(T(u))^2 - \alpha_2 \left(\frac{R_d(u)}{100} \right)^2, & \text{CRI maximization} \end{cases} \quad (7)$$

$$\text{subject to} \quad y_d - y_{\text{dark}} \leq \mathbf{G} \mathbf{u} \leq (1 + \beta)(y_d - y_{\text{dark}}) \quad \text{and} \quad \mathbf{0} \leq \mathbf{u} \leq \mathbf{1}.$$

where $\mathbf{u} = [u_1, \dots, u_p]^T$ is the input intensity vector for the p LED channels, Γ_E is a row vector consisting of the power consumption of

each LED channel in the full-on state, P_t is the maximum power consumption for an individual light fixture, α_1 and α_2 are weights, while y_d

and y_{dark} are respectively the desired minimum illumination and ambient illumination measured at the sensor node position and $\mathbf{G} \in \mathbb{R}^{qm \times pn}$ is the LTM. The linear constraints ensure that the achieved illumination level on the work space falls within a certain boundary (defined by the parameter β) around the desired minimum illumination level y_d . An off-the-shelf solver was used to determine the optimum input intensity $\mathbf{u}^{opt}$ satisfying all the constraints specified in (7). This algorithm does not take the spatial variation of the light field into account and is suitable for a single light source and sensor.

Hierarchical Optimization for Multichannel LEDs

In many applications, the number of source channels is larger than the number of sensor channels (which are typically limited to RGB). Afshari and Mishra (2015) proposed an optimization-based framework for control of such systems, which exploits the inherent control redundancy due to the color metamerisms. The optimization problem is posed as determination of the appropriate light input to minimize the weighted sum of illumination quality and energy consumption.

Given the LTM, $\mathbf{G} \in \mathbb{R}^{qm \times pn}$, as described in section “[Light Transport Modeling](#)”, and a vector $y_d \in \mathbb{R}^{qm}$ consisting of the desired RGB values for each of the sensors, the light quality metric was formulated as the Euclidean norm of the difference between the desired and measured sensor values (y_d and y). On the other hand, the performance metric was formulated as a function of the input intensities (u) that might optimize different performance parameters, such as power efficiency, CRI, or CCT. The controller design problem is formulated as:

$$\begin{aligned} \mathbf{u}^{opt} = \underset{\mathbf{u}}{\operatorname{argmin}} \quad & \|y_d - y_k\|_2^2 + \alpha_f f(\mathbf{u}_k) \\ \text{subject to} \quad & 0 \leq u \leq 1 \end{aligned} \quad (8)$$

where $\mathbf{u} = [u_1, u_2, \dots, u_{pn}]^T$ consists of the input intensities of the light fixtures, $f(\mathbf{u})$ denotes a user-defined performance metric, and α_f is a weighting coefficient. u_k and y_k denote

the input intensity and RGB sensor measurement at k -th time-step, respectively.

The optimization problem in (8) can be solved using a *two-step hierarchical approach*. In the first step, a candidate solution ($\bar{u}_k$) to drive the output of the system toward the desired light field is calculated using a gradient based method. The update equation for this step is:

$$\bar{u}_k = u_k + \epsilon G^T (G G^T)^{-1} (y_d - y_k), \quad (9)$$

where ϵ is the step size. Since the system has more source channels than sensor channels, the redundancy in the generation of color results in the existence of an infinite number of candidate solutions, all resulting in the same sensor reading. Each of these solutions may successfully achieve the desired color set point, as long as y_d is a feasible target. This creates the opportunity for further optimization of the system performance within the set of all the candidate solutions.

In the next step, another optimization problem is solved to find the input intensity vector from the set of all candidate solutions that optimizes the user-defined performance metric. This optimal solution, u , is obtained using the following equation:

$$u_{k+1} = \bar{u}_k - G_N w \quad (10)$$

where G_N is an orthogonal matrix the columns of which span the null space of G and the w is obtained from solving the following optimization problem:

$$\min_w f(u - G_N w)$$

$$\text{subject to} \quad 0 \leq (u - G_N w)(i) \leq 1, \quad i=1, \dots, pn. \quad (11)$$

As an example of the user-defined performance metric $f(u)$, we can choose to optimize the total power consumption of the system. Assuming that the power consumption of individual LED channels of the fixtures can be approximated as a linear function of the channel's input intensity, $f(u) = \Gamma_E u$, where

Γ_E represents the power consumption of the individual LED channels in full-on state. The hierarchical approach results in convergence to the power-efficient solution that achieves y_d . Note that this approach ensures zero steady state error as well as power minimization, as opposed to trading off light quality for power saving.

Summary and Conclusion

This chapter provides an overview of various existing feedback control algorithms for LED-based lighting systems. In order to choose a particular feedback control strategy for smart lighting systems, some of the questions that need to be addressed are whether the lighting system is single-color or color-tunable, whether the multichannel color sensing and occupancy sensing technologies are available, whether the sensors are at the ceiling or at the work space in the illuminated space, what is the accuracy and speed of the sensors, etc. With advances in computation, sensing, and communication technologies, lighting systems may be flexibly adapted and reconfigured to specific requirements by switching between various methodologies. These advanced smart lighting systems, interconnected with other building systems, can in fact be used to provide new services for an office building beyond illumination.

Cascading Network Failure in Power Grid Blackouts

Ian Dobson
Iowa State University, Ames, IA, USA

Abstract

Cascading failure consists of complicated sequences of dependent failures and can cause large blackouts. The emerging risk analysis, simulation, and modeling of cascading blackouts are briefly surveyed, and key references are suggested.

Keywords

Outage · Branching process · Simulation · Dependent failures · Risk · Power law

Introduction

The main mechanism for the rare and costly widespread blackouts of bulk power transmission systems is cascading failure. Cascading failure can be defined as a sequence of dependent events that successively weaken the power system (IEEE PES CAMS Task Force on Cascading Failure 2008). The events and their dependencies are very varied and include outages or failures of many different parts of the power system and a whole range of possible physical, cyber, and

human interactions. The events and dependencies tend to be rare or complicated, since the common and straightforward failures tend to be already mitigated by engineering design and operating practice.

Examples of a small initial outage cascading into a complicated sequence of dependent outages are the August 10, 1996, blackout of the Northwest United States that disconnected power to about 7.5 million customers (Kosterev et al. 1999), the August 2003 blackout of about 50 million customers in Northeastern United States and Canada (US-Canada Power System Outage Task Force 2004), and the September 2011 San Diego blackout (Federal Energy Regulatory Commission 2012). Although such extreme events are rare, the direct costs can run to billions of dollars and the disruption to society is substantial. Large blackouts also have a strong effect on shaping the way power systems are regulated and the reputation of the power industry. Moreover, some blackouts involve social disruptions that can multiply the economic damage. The hardship to people and possible deaths underscore the engineer's responsibility to work to avoid blackouts.

It is useful when analyzing cascading failure to consider cascading events of all sizes, including the short cascades that do not lead to interruption of power to customers and cascades that involve events in other infrastructures, especially since loss of electricity can significantly impair other essential or economically important infrastructures. Note that in the context of

interacting infrastructures, the term “cascading failure” sometimes has the more restrictive definition of events cascading *between* infrastructures (Rinaldi et al. 2001).

Blackout Risk

Cascading failure is a sequence of dependent events that successively weaken the power system. At a given stage in the cascade, the previous events have weakened the power system so that further events are more likely. It is this dependence that makes the long series of cascading events that cause large blackouts likely enough to pose a substantial risk. (If the events were independent, then the probability of a large number of events would be the product of the small probabilities of individual events and would be vanishingly small.) The statistics for the distribution of sizes of blackouts have correspondingly “heavy tails” indicating that blackouts of all sizes, including large blackouts, can occur. Large blackouts are rare, but they are expected to happen occasionally, and they are not “perfect storms.”

In particular, it has been observed in several developed countries that the probability distribution of blackout size has an approximate power law dependence (Carreras et al. 2004b, 2016; Dobson et al. 2007; Hines et al. 2009). (The power law is of course limited in extent because every grid has a largest possible blackout in which the entire grid blacks out.) The power law region can be explained using ideas from complex systems theory. The main idea is that over the long term, the power grid reliability is shaped by the engineering responses to blackouts and the slow load growth and tends to evolve toward the power law distribution of blackout size (Dobson et al. 2007; Ren et al. 2008).

Blackout risk can be defined as the product of blackout probability and blackout cost. One simple assumption is that blackout cost is roughly proportional to blackout size, although larger blackouts seem to have costs (especially indirect costs) that increase faster than linearly. In the case of the power law dependence, the larger blackouts can become rarer at a similar

rate as costs increase, and then the risk of large blackouts is comparable to or even exceeding the risk of small blackouts (Carreras et al. 2016). Mitigation of blackout risk should consider both small and large blackouts, because mitigating the small blackouts that are easiest to analyze may inadvertently increase the risk of large blackouts (Newman et al. 2011).

Approaches to quantify blackout risk are challenging and emerging, but there are also valuable approaches to mitigating blackout risk that do not quantify the blackout risk. The n-1 criterion that requires the power system to survive any single component failure has the effect of reducing cascading failures. The individual mechanisms of dependence in cascades (overloads, protection failures, voltage collapse, transient stability, lack of situational awareness, human error, etc.) can be addressed individually by specialized analyses or simulations or by training and procedures. Credible initiating outages can be sampled and simulated, and those resulting in cascading can be mitigated (Hardiman et al. 2004). This can be thought of as a “defense in depth” approach in which mitigating a subset of credible contingencies is likely to mitigate other possible contingencies not studied. Moreover, when blackouts occur, a postmortem analysis of that particular sequence of events leads to lessons learned that can be implemented to mitigate the risk of some similar blackouts (US-Canada Power System Outage Task Force 2004).

Simulation and Models

There are many simulations of cascading blackouts using Monte Carlo and other methods, for example, Hardiman et al. (2004), Carreras et al. (2004a), Chen et al. (2005), Kirschen et al. (2004), Anghel et al. (2007), and Bienstock and Mattia (2007). All these simulations select and approximate a modest subset of the many physical and engineering mechanisms of cascading failure, such as line overloads, voltage collapse, and protection failures. In addition, operator actions or the effects of engineering the network may also be crudely represented. Some

of the simulations give a set of credible cascades, and others approximately estimate blackout risk.

Except for describing the initial outages, where there is a wealth of useful knowledge, much of standard risk analysis and modeling does not easily apply to cascading failure in power systems because of the variety of dependencies and mechanisms, the combinatorial explosion of rare possibilities, and the heavy-tailed probability distributions. However, progress has been made in probabilistic models of cascading (Chen et al. 2006; Dobson 2012; Rahnamay-Naeini et al. 2012).

The goal of high-level probabilistic models is to capture salient features of the cascade without detailed models of the interactions and dependencies. They provide insight into cascading failure data and simulations, and parameters of the high-level models can serve as metrics of cascading.

Branching process models are transient Markov probabilistic models in which, after some initial outages, the outages are produced in successive generations. Each outage in each generation (a “parent” outage) produces a probabilistic number of outages (“children” outages) in the next stage according to an offspring probability distribution. The children failures then become parents to produce the next generation and so on, until there is a generation with zero children and the cascade stops. As might be expected, a key parameter describing the cascading is its average propagation, which is the average number of children outages per parent outage. Branching processes have traditionally been applied to many cascading processes outside of risk analysis (Harris) and have been applied to estimate the distribution of the total number of outages from utility outage data (Dobson 2012). A probabilistic model that tracks the cascade as it progresses in time through lumped grid states is presented in Rahnamay-Naeini et al. (2012). The interactions between line outages are described in a probabilistic influence network different than the grid network in Hines et al. (2017).

There is an extensive complex networks literature on cascading in abstract networks that is largely motivated by idealized models of propagation of failures in the Internet. The way that

failures propagate only along the network links is not realistic for power systems, which satisfy Kirchhoff’s laws so that many types of failures propagate differently. For example, line overloads tend to propagate along cutsets of the network, and there are both short-range and long-range interactions between outages (Dobson et al. 2016; Hines et al. 2017). However, the high-level qualitative results of phase transitions in the complex networks have provided inspiration for similar effects to be discovered in power system models (Dobson et al. 2007).

Summary and Future Directions

One challenge for simulation is what selection of phenomena to model and in how much detail in order to get useful and validated engineering results (IEEE Working Group on Cascading Failures 2016). Faster simulations would help to ease the requirements of sampling appropriately from all the sources of uncertainty. Better metrics of cascading in addition to average propagation need to be developed and extracted from real and simulated data in order to better quantify and understand blackout risk. There are many new ideas emerging to analyze and simulate cascading failure, and the next step is to validate and improve these new approaches by comparing them with observed blackout data. Overall, there is an exciting challenge to build on the more deterministic approaches to mitigate cascading failure and find ways to more directly quantify and mitigate cascading blackout risk by coordinated analysis of real data, simulation, and probabilistic models.

Cash Management

Abel Cadenillas

University of Alberta, Edmonton, AB, Canada

Abstract

Cash on hand (or cash held in highly liquid form in a bank account) is needed for routine business and personal transactions. The problem of determining the right amount of cash to hold involves balancing liquidity against investment opportunity costs. This entry traces solutions using both discrete-time and continuous-time stochastic models.

Keywords

Brownian motion · Inventory theory ·
Stochastic impulse control

Definition

A firm needs to keep cash, either in the form of cash on hand or as a bank deposit, to meet its daily transaction requirements. Daily inflows and outflows of cash are random. There is a finite target for the cash balance, which could be zero in some cases. The firm wants to select a policy that minimizes the expected total discounted cost for being far away from the target during some time horizon. This time horizon is usually infinity. The firm has an incentive to keep the cash level low, because each unit of positive cash leads to a holding cost since cash has alternative uses like dividends or investments in earning assets. The firm has an incentive to keep the cash level high, because penalty costs are generated as a result of delays in meeting demands for cash. The firm can increase its cash balance by raising new capital or by selling some earnings assets, and it can reduce its cash balance by paying dividends or investing in earning assets. This control of the cash balance generates fixed and proportional transaction costs. Thus, there is a cost when the cash balance is different from its target, and there is also a cost for increasing or reducing the cash reserve. The objective of the manager is to minimize the expected total discounted cost.

Hasbrouck (2007), Madhavan and Smidt (1993), and Manaster and Mann (1996) study inventories of stocks that are similar to the cash management problem.

The Solution

The qualitative form of optimal policies of the cash management problem in discrete time was studied by Eppen and Fama (1968, 1969), Girgis (1968), and Neave (1970). However, their solutions were incomplete.

Many of the difficulties that they and other researchers encountered in a discrete-time framework disappeared when it was assumed that decisions were made continuously in time and that demand is generated by a Brownian motion with drift. Vial (1972) formulated the cash management problem in continuous time with fixed and proportional transaction costs, linear holding and penalty costs, and demand for cash generated by a Brownian motion with drift. Under very strong assumptions, Vial (1972) proved that if an optimal policy exists, then it is of a simple form (a, α, β, b) .

This means that the cash balance should be increased to level α when it reaches level a and should be reduced to level β when it reaches level b . Constantinides (1976) assumed that an optimal policy exists and it is of a simple form and determined the above levels and discussed the properties of the optimal solution. Constantinides and Richard (1978) proved the main assumptions of Vial (1972) and therefore obtained rigorously a solution for the cash management problem.

Constantinides and Richard (1978) applied the theory of stochastic impulse control developed by Bensoussan and Lions (1973, 1975, 1982). They used a Brownian motion W to model the uncertainty in the inventory. Formally, they considered a probability space $(\Omega, \mathcal{F}, P)$ together with a filtration $(\mathcal{F}_t)$ generated by a one-dimensional Brownian motion W . They considered

X_t := inventory level at time t and assumed that X is an adapted stochastic process given by

$$X_t = x - \int_0^t \mu ds - \int_0^t \sigma dW_s + \sum_{i=1}^{\infty} I_{\{\tau_i < t\}} \xi_i.$$

Here, $\mu > 0$ is the drift of the demand and $\sigma > 0$ is the volatility of the demand. Furthermore, τ_i is the time of the i -th intervention and ξ_i is the intensity of the i -th intervention.

A stochastic impulse control is a pair

$((\tau_n); (\xi_n))$

$= (\tau_0, \tau_1, \tau_2, \dots, \tau_n, \dots; \xi_0, \xi_1, \xi_2, \dots, \xi_n, \dots),$

where

$$\tau_0 = 0 < \tau_1 < \tau_2 < \dots < \tau_n < \dots$$

is an increasing sequence of stopping times and (ξ_n) is a sequence of random variables such that each $\xi_n : \Omega \mapsto \mathbf{R}$ is measurable with respect to $\mathcal{F}_{\tau_n}$. We assume $\xi_0 = 0$. The management (the controller) decides to act at time

$$X_{\tau_i^+} = X_{\tau_i} + \xi_i.$$

We note that ξ_i and X can also take negative values. The management wants to select the pair

$$((\tau_n); (\xi_n))$$

that minimizes the functional J defined by

$$J(x; ((\tau_n); (\xi_n))) := E \left[\int_0^\infty e^{-\lambda t} f(X_t) dt + \sum_{n=1}^\infty e^{-\lambda \tau_n} g(\xi_n) I_{\{\tau_n < \infty\}} \right],$$

where

$$f(x) = \max(hx, -px)$$

and

$$g(\xi) = \begin{cases} C + c\xi & \text{if } \xi > 0 \\ \min(C, D) & \text{if } \xi = 0 \\ D - d\xi & \text{if } \xi < 0 \end{cases}$$

Furthermore, $\lambda > 0, C, c, D, d \in (0, \infty)$, and $h, p \in (0, \infty)$. Here, f represents the running cost incurred by deviating from the aimed cash level 0, C represents the fixed cost per intervention when the management pushes the cash level upwards, D represents the fixed cost per intervention when the management pushes the cash level downwards, c represents the proportional cost per intervention when the management pushes the cash level upwards, d represents the proportional cost per intervention when the management pushes the cash level downwards, and λ is the discount rate.

The results of Constantinides and Richard (1978) were complemented, extended, or improved by Baccarin (2009), Bar-Ilan et al.

(2004), Cadenillas et al. (2010), Cadenillas and Zapatero (1999), Feng and Muthuraman (2010), Harrison et al. (1983), and Ormeci et al. (2008).

Abstract

A review of characteristics-based approaches to optimal control computation is presented for nonlinear deterministic systems described by ordinary differential equations. We recall Pontryagin's principle which gives necessary optimality conditions for open-loop control strategies. The related framework of generalized characteristics for first-order Hamilton–Jacobi–Bellman equations is discussed as a theoretical tool that bridges the gap between the necessary and sufficient optimality conditions. We point out widely used numerical techniques for obtaining optimal open-loop control strategies (in particular for state-constrained problems) and how indirect (characteristics based) and direct methods may reasonably be combined. A possible transition from open-loop to feedback constructions is also described. Moreover, we discuss approaches for attenuating the curse of dimensionality for certain classes of Hamilton–Jacobi–Bellman equations.

Optimal control · Pontryagin's principle · Hamilton–Jacobi–Bellman equations · Method of characteristics · Indirect and direct numerical approaches · State constraints · Curse of dimensionality

Introduction

Optimal control problems for dynamical systems described by ordinary differential equations have various applications in science and engineering (Afanas'ev et al. 1996; Pesch 1994; Trélat 2012; Schättler and Ledzewicz 2015). One has to distinguish between the classes of open-loop and feedback (closed-loop) control strategies; the former are functions of time, while the latter are functions of time and state. In comparison with optimal open-loop control strategies, optimal feedback control strategies are typically more advantageous in practice, since they are applicable to all considered initial states and more robust with respect to uncertainties.

It is common to distinguish between two groups of numerical approaches to constructing optimal open-loop control strategies: direct and indirect methods (Grüne 2014; Pesch 1994; Trélat 2012; Benson et al. 2006; Rao 2010; Cristiani and Martinon 2010). Direct methods involve the direct transcriptions of infinite-dimensional optimal open-loop control problems to finite-dimensional nonlinear programming problems via discretizations in time applied to state and control variables, as well as to dynamical state equations. Indirect methods employ Pontryagin's principle (Pontryagin et al. 1964; Cesari 1983; Yong and Zhou 1999; Schättler 2014). Comparatively, direct methods are in principle less precise and less justified from a theoretical perspective than indirect methods but are often more robust with respect to initialization and more straightforward to use.

For describing optimal feedback control strategies, Hamilton–Jacobi–Bellman partial differential equations (HJB PDEs) and sufficient optimality conditions constitute a fundamental

theoretical framework (Fleming and Soner 2006; Bardi and Capuzzo-Dolcetta 2008; Subbotin 1995; Melikyan 1998; Yong and Zhou 1999). Exact solutions of boundary value, initial value, and mixed problems for HJB PDEs are known only in very special cases. Many widely used numerical approaches to solving these problems, including semi-Lagrangian schemes (Bardi and Capuzzo-Dolcetta 2008; Bokanowski et al. 2017), finite-difference schemes (Fleming and Soner 2006; Kushner and Dupuis 2001; Bokanowski et al. 2017), finite element methods (Jensen and Smears 2013), and level set methods (Osher and Fedkiw 2003), typically rely on dense state space discretizations. Where a problem for an HJB PDE is stated in an unbounded domain of the state space, one has to select an appropriate bounded subdomain for discretization and computation (which is often a heuristic choice); see, e.g., (Fleming and Soner 2006; Kushner and Dupuis 2001; Bardi and Capuzzo-Dolcetta 2008). A more critical aspect is that the computational cost of such grid-based numerical methods grows exponentially with the increase of the state space dimension, so that their feasible implementation is in general extremely limited (even on supercomputers) if the state space dimension is greater than 3. This leads to what R. Bellman called the curse of dimensionality (Bellman 1957). Attenuating the curse of dimensionality for various classes of HJB PDEs and also more general Hamilton–Jacobi (HJ) PDEs, such as Hamilton–Jacobi–Isaacs (HJI) PDEs for zero-sum two-player differential games, has therefore become an important research area. A number of related approaches have been developed for particular classes of problems; see, e.g., the corresponding overview in Yegorov and Dower (2018). It is emphasized that, even if the curse of dimensionality is mitigated, the so-called curse of complexity may still cause significant issues in numerical implementation (McEneaney 2006; McEneaney and Kluberg 2009; Kang and Wilcox 2017).

A relevant direction for attenuating the curse of dimensionality for certain classes of first-order HJ equations is to reduce the

evaluation of their solutions at any selected states to finite-dimensional optimization (nonlinear programming) problems (Darbon and Osher 2016; Chow et al. 2017; Kang and Wilcox 2017). In contrast with many grid-based methods, this leads to the following advantages:

- the solutions can be evaluated independently at different states, which allows for attenuating the curse of dimensionality;
- since different states are separately treated, one can choose arbitrary bounded regions and grids for computations and arrange parallelization;
- when obtaining the value function, i.e., the solution of an HJB or HJI equation, at selected states by solving the related finite-dimensional optimization problems, one can usually retrieve the corresponding control actions without requiring possibly unstable approximations of the partial derivatives of the value function.

However, the curse of complexity can ensue if the considered nonlinear programming problem is essentially multi-extremal or if one wants to construct a global or semi-global solution approximation in a high-dimensional region. Sparse grid frameworks can be helpful for the latter purpose in some cases (Kang and Wilcox 2017). Other approaches to mitigating the curse of dimensionality and the curse of complexity for certain classes of nonlinear optimal control problems include methods based on the max- and min-plus algebras and corresponding idempotent analysis (McEneaney 2006; McEneaney and Kluberg 2009).

The finite-dimensional optimization problems that describe the values at arbitrary isolated states of the solutions of first-order HJB equations can build on the aforementioned direct and indirect approaches to approximating optimal open-loop control strategies. Note also that the indirect approaches using Pontryagin’s principle relate to the (generalized) method of characteristics for such nonlinear first-order PDEs and can hence be called characteristics based. The

method of characteristics often serves as a theoretical tool that bridges the gap between the necessary and sufficient optimality conditions (Subbotin 1995; Melikyan 1998; Subbotina 2006). The purpose of this entry is to review some existing and recent developments regarding the characteristics-based approaches to optimal control computation.

Pontryagin's Principle and Characteristics

We start with a discussion of Pontryagin's principle (Pontryagin et al. 1964; Cesari 1983; Yong and Zhou 1999; Hartl et al. 1995). For simplicity, consider a deterministic time-invariant system given by

$$\begin{cases} \dot{x}(t) = f(x(t), u(t)), & u(t) \in U, & t \in I, \\ I = [0, T] \text{ in case of fixed terminal time } T, \text{ and } I = [0, +\infty) \text{ if } T \text{ is free,} \\ x(0) = x_0 \in G \text{ is fixed,} \\ \mathcal{U} \text{ is the class of measurable open-loop control functions } u: I \rightarrow U, \end{cases} \quad (1)$$

with the terminal constraint

$$x(T) \in \Omega \quad (2)$$

and with the objective of minimizing a Bolza functional over admissible open-loop control strategies:

$$\varphi(x(T)) + \int_0^T \ell(x(t), u(t)) dt \longrightarrow \min. \quad (3)$$

In (1), (2), and (3), $t \geq 0$, $x(t) \in \mathbb{R}^{n \times 1}$, and $u(t) \in \mathbb{R}^{m \times 1}$ are the time, state, and control variables, respectively; both cases of fixed and free terminal time T are incorporated, and the following are assumed:

- $U \subset \mathbb{R}^m$ is a closed convex set that specifies pointwise control constraints, and $G \subseteq \mathbb{R}^n$ is an open domain in the state space;
- the functions $f: \bar{G} \times U \rightarrow \mathbb{R}^n$, $\varphi: \bar{G} \rightarrow \mathbb{R}$, and $\ell: \bar{G} \times U \rightarrow \mathbb{R}$ are continuous ($\bar{G}$ denotes the closure of G), and they are also continuously differentiable with respect to the state variable in G ;
- G is a strongly invariant domain in the sense that any state trajectory of (1) with $x_0 \in G$ and $u(\cdot) \in \mathcal{U}$ does not leave G ($G = \mathbb{R}^n$ is a trivial example of a strongly invariant domain);

- for any $x_0 \in G$ and $u(\cdot) \in \mathcal{U}$, there exists a unique solution $x: I \rightarrow \mathbb{R}^n$ of (1);
- $\Omega \subseteq \mathbb{R}^n$ is a closed terminal set in the state space.

We refer to Cesari (1983) for a survey of sufficient conditions for the existence of optimal open-loop control strategies in various classes of problems.

The Hamiltonian is defined by

$$\begin{aligned} H(x, u, p, \tilde{p}) &= \langle p, f(x, u) \rangle + \tilde{p} \ell(x, u) \\ \forall (x, u, p, \tilde{p}) &\in G \times U \times \mathbb{R}^n \times \mathbb{R}, \end{aligned} \quad (4)$$

where $p \in \mathbb{R}^{n \times 1}$ is the so-called costate or adjoint variable. Pontryagin's (minimum) principle states that, if $(u^*(\cdot), x^*(\cdot), T^*)$ is an optimal process for the problem (1), (2), and (3), there exist a function $p^*: [0, T^*] \rightarrow \mathbb{R}^{n \times 1}$ and a constant $\tilde{p}^* \geq 0$ such that the following properties hold:

- $(p^*(t), \tilde{p}^*)$ is nonzero for every $t \in [0, T^*]$;
- $(x^*(\cdot), p^*(\cdot))$ is an absolutely continuous solution of the characteristic system

$$\begin{aligned} \dot{x}^*(t) &= H_p(x^*(t), u^*(t), p^*(t), \tilde{p}^*) \\ &= f(x^*(t), u^*(t)), \end{aligned}$$

$$\dot{p}^*(t) = -H_x(x^*(t), u^*(t), p^*(t), \tilde{p}^*) \quad (5)$$

on $[0, T^*]$ with the boundary conditions

$$\begin{aligned} x^*(0) &= x_0, \quad x^*(T^*) \in \Omega, \\ p^*(T^*) &= \tilde{p}^* \varphi_x(x^*(T^*)) \\ &\in N(x^*(T^*); \Omega), \end{aligned} \quad (6)$$

where $N(x^*(T^*); \Omega)$ denotes the normal cone to Ω at $x^*(T^*)$, which is polar to the related tangent cone (Clarke et al. 1998, §2.5);

- the Hamiltonian minimum condition

$$\begin{aligned} H(x^*(t), u^*(t), p^*(t), \tilde{p}^*) \\ = \min_{w \in U} H(x^*(t), w, p^*(t), \tilde{p}^*) \end{aligned} \quad (7)$$

is satisfied for almost all $t \in [0, T^*]$ (with respect to the Lebesgue measure);

- if the terminal time is not fixed in the problem formulation, the Hamiltonian vanishes along the optimal process, i.e., $H(x^*(t), u^*(t), p^*(t), \tilde{p}^*) = 0$ for almost all $t \in [0, T^*]$.

For example, the terminal costate $p^*(T^*)$ is free if Ω is a singleton, while $p^*(T^*) = \tilde{p}^* \varphi_x(x^*(T^*))$ if $\Omega = \mathbb{R}^n$. A solution of the system (1) satisfying the Hamiltonian minimum condition (7) and such that $(p^*(t), \tilde{p}^*)$ does not vanish is called a characteristic (regardless of whether the boundary conditions (6) are fulfilled or not), in line with the generalized method of characteristics for first-order HJB

PDEs (Subbotin 1995; Melikyan 1998; Subbotina 2006). A characteristic fully satisfying Pontryagin's principle is called extremal. We say that a characteristic with $\tilde{p}^* = 0$ is abnormal, while $\tilde{p}^* > 0$ indicates a normal characteristic. A singular arc of a characteristic occurs when the set of minimizers in (7) is not a singleton on a time subinterval.

The value function in the optimal control problem (1), (2), and (3) maps the initial state x_0 to the infimum of the cost functional. This particular problem is formulated with zero initial instant $t_0 = 0$, but, in general, the value function depends on both t_0 and $x_0 = x(t_0)$ (and the integral in (3) is taken over $[t_0, T]$). Value functions satisfy HJB equations in the viscosity sense and may be nonsmooth (Fleming and Soner 2006; Bardi and Capuzzo-Dolcetta 2008; Yong and Zhou 1999). A number of verification theorems as well as relations between the costate components of extremal characteristics and the super- and subdifferentials of value functions have been established; see, e.g., Yong and Zhou (1999, Chapter 5). Such results in fact serve as a theoretical connection between Pontryagin's principle (necessary optimality conditions) and HJB equations (used in sufficient optimality conditions). Note that the mentioned relations are markedly simplified where value functions are differentiable (so that the super- and subdifferentials are reduced to the gradients).

In the specific case of fixed terminal time T and free terminal state ($\Omega = \mathbb{R}^n$), the Cauchy problem for the HJB equation in the problem (1), (2), and (3) is formally written as follows:

$$\begin{cases} -\frac{\partial V(x, t)}{\partial t} + \sup_{w \in U} \left\{ -\left\langle \frac{\partial V(x, t)}{\partial x}, f(x, w) \right\rangle - \ell(x, w) \right\} = 0, & (x, t) \in G \times [0, T), \\ V(x, T) = \varphi(x), & x \in G. \end{cases}$$

Pontryagin's principle has been extended to certain classes of optimal control problems with state constraints, leading to a number of new possible features of related characteristics, in particular junctions and contacts with

state-constraint boundaries, boundary arcs, as well as costate jumps (Schättler 2014; Hartl et al. 1995; Maurer 1977; Bonnard et al. 2003; Pesch 1994; Cristiani and Martinon 2010; Basco et al. 2018).

Characteristics-Based Approaches to Approximating Optimal Open-Loop Control Strategies

For simplicity, consider an optimal open-loop control problem as formulated in the previous section, or, in order to address a state-constrained case as well, its modification to include a scalar pure state inequality constraint of finite order and under the additional assumptions of scalar control input and control-affine dynamical equations (Maurer 1977; Bonnard et al. 2003; Pesch 1994; Cristiani and Martinon 2010). Pontryagin's principle allows for reducing the studied problem to a characteristic boundary value problem with accompanying conditions. It is typical to suppose that the Hamiltonian minimum condition determines the extremal control action as a single-valued function of the state x and extended costate $(p, \tilde{p})$ almost everywhere outside singular and constrained boundary arcs which have to be separately investigated. The analysis of the singular and boundary arcs can also provide the related representations of the control u and constraint-based Lagrange multiplier function η in terms of $x, p, \tilde{p}$ (Maurer 1977; Bonnard et al. 2003; Pesch 1994; Cristiani and Martinon 2010), and this is assumed here.

For computational purposes, the characteristic boundary value problem can be stated with a finite number of unknowns, even though the original control problem is infinite-dimensional. The first unknown in the characteristic boundary value problem is the initial costate $p(0)$. Due to the homogeneity of the Hamiltonian with respect to $(p, \tilde{p}, \eta)$, the normal case $\tilde{p} > 0$ can be reduced to $\tilde{p} = 1$, while the abnormal case $\tilde{p} = 0$ must be separately treated. The abnormal case is sometimes excluded a priori from practical consideration, since the Hamiltonian (4) does not depend on the running cost $\ell(x, u)$ for $\tilde{p} = 0$. Alternatively, one can consider $(p(0), \tilde{p})$ as an unknown vector on the unit sphere in $\mathbb{R}^{n+1}$. Bearing in mind the Hamiltonian conservation property for time-invariant control systems, the Hamiltonian vanishing condition in case of free terminal time T can be imposed just at $t = T$.

An unconstrained singular arc adds unknown entry and exit times together with the corresponding junction conditions to the characteristic boundary value problem. Note that, for a system with scalar control input and control-affine dynamical equations, the coefficient for the control in the Hamiltonian is called the switching function. Moreover, if a singular arc is of first order, i.e., if the control variable explicitly appears in the second total time derivative of the switching function (such an appearance may in general take place first for an even derivative), then the junction conditions can be specified at the entry time as vanishing of the switching function together with its first total time derivative (Pesch 1994; Cristiani and Martinon 2010; Bonnard et al. 2003).

Note also that, for certain classes of problems, singular regimes can be excluded for normal characteristics if one adds a small regularizing term such as a control-dependent positive definite quadratic form to the running cost, so that the Hamiltonian minimum condition leads to a single-valued extremal control map in the normal case.

A boundary arc adds unknown entry and exit times together with the junction conditions, Hamiltonian continuity, and costate jump conditions at the entry and exit times, and the costate jump parameters are other unknowns which may nevertheless be described by analytical representations in certain cases (Maurer 1977; Bonnard et al. 2003). Expected contacts with the constraint boundary can be treated similarly.

Thus, solving the characteristic boundary value problem corresponds to finding the unknown parameters leading to an extremal characteristic that satisfies all terminal and path constraints. This is usually done via the numerical approach of multiple shooting (Grüne 2014; Rao 2010; Bonnard et al. 2003; Trélat 2012; Pesch 1994; Cristiani and Martinon 2010). It in particular requires a priori guesses for the numbers of unconstrained singular arcs, constrained boundary arcs, and contacts with the constraint boundary on a sought-after characteristic. The numerical efficiency can in principle be improved

if one uses an indirect collocation method so that the state and costate trajectories are parametrized via specific piecewise polynomial functions (Rao 2010; Kang and Wilcox 2017). Such methods include local collocation and global collocation. For local collocation, the degrees of local polynomials are fixed and the number of meshes is varied to improve accuracy. On the other hand, global collocation fixes the number of meshes and varies the degree of a global polynomial to improve accuracy.

The characteristic boundary value problem may have multiple solutions for the initial states at which the state components of some characteristics with different terminal states intersect each other and the value function is therefore expected to be nonsmooth (Yong and Zhou 1999, Chapters 4, 5). This may cause a practical dilemma of how to retrieve optimal characteristics for some initial states in small neighborhoods of switching manifolds and near constraint boundaries. A number of studies hence proposed to replace the terminal costate condition with the cost optimization criterion, leading to constrained nonlinear programming instead of constrained root-finding (Yegorov and Dower 2018; Darbon and Osher 2016). Figure 1 is taken from Yegorov and Dower (2018, Example 5.1) and compares the numerical results of solving the optimization and boundary value problems for the characteristics of a particular Eikonal type HJB PDE.

Since indirect (characteristics based) methods for approximating optimal open-loop control strategies are often rather sensitive with respect to initialization, more robust direct methods may serve as an auxiliary tool for finding appropriate initial conditions (Pesch 1994; Cristiani and Martinon 2010; Trélat 2012).

Related efforts in the development of spectral methods for fluid dynamics have led to a class of direct numerical approaches referred to as pseudospectral methods that allow for costate estimation and find application in a range of practical problems (Benson et al. 2006; Huntington et al. 2007; Rao 2010). A pseudospectral method involves global orthogonal collocation. That is, the state and control variables are parametrized

via a basis of global polynomials, the dynamics are collocated at a specific set of points on the observed time interval, and the collocation points are chosen as the roots of an orthogonal polynomial or linear combinations of such polynomials and their derivatives. For smooth problems, these methods exhibit the so-called spectral accuracy that can be a precursor to fast convergence. Non-smooth problems can be divided into phases so that orthogonal collocation is applied globally within each phase. For example, the Gauss pseudospectral method uses global Lagrange polynomials and Legendre–Gauss points for collocation, and it differs from several other pseudospectral methods in that the dynamics are not collocated at the boundary points. This choice of collocation, together with an appropriate Lagrange polynomial approximation of the costate variable, leads to the Karush–Kuhn–Tucker conditions that are identical to the discretized form of the first-order necessary optimality conditions (Pontryagin’s principle) at the Legendre–Gauss points. Thus, the Karush–Kuhn–Tucker multipliers of the direct nonlinear programming problems can be used to estimate the costate components of the extremal characteristics at the collocation points as well as at the boundary points. Figure 2 is a schematic illustration of this costate estimation technique. More details can be found in Benson et al. (2006), Huntington et al. (2007), and Rao (2010).

Transition from Open-Loop to Feedback Constructions

As was discussed in the introduction, reducing the computation of value functions and optimal control actions at selected states to finite-dimensional nonlinear programming problems, e.g., by solving optimal open-loop control problems via indirect (characteristics based) or direct methods, helps to attenuate the curse of dimensionality for HJB PDEs. It was however noted that the curse of complexity can represent a formidable barrier to global or semi-global approximation of sought-after functions in high-dimensional regions. Moreover, the curse of

Characteristics in Optimal Control Computation,

Fig. 1 These illustrations are reproduced from Yegorov and Dower (2018, Example 5.1). (Permission granted by Springer Nature under Copyright Clearance Center's RightsLink® license number 4641070769945). They correspond to a certain nonlinear optimal control problem whose value function is a unique viscosity solution of a Cauchy problem for an Eikonal type first-order HJB PDE. The state space is two-dimensional, and the goal is to maximize a Mayer cost functional. The value function was computed via the following three different approaches: (i) optimization over the characteristic Cauchy problems, (ii) solving the characteristic boundary value problems, and (iii) solving the Cauchy problem for the HJB PDE via a finite-difference scheme. The related value function approximations are denoted by V_{MoC} , $V_{MoC,BVP}$, and V_{FD} , respectively (the abbreviations “MoC”, “BVP”, and “FD” stand for “method of characteristics”, “boundary

value problem”, and “finite differences”). The upper two subfigures illustrate a section of V_{MoC} for a fixed time with some of its level sets. The lower left and lower right subfigures show, respectively, the differences $V_{MoC} - V_{MoC,BVP}$ and $V_{MoC} - V_{FD}$ at the same fixed time (in order to see these graphs clearer, essentially larger scales for the vertical axis are used). One has $V_{MoC} \geq V_{MoC,BVP}$ due to the maximization criterion and how the approaches are stated. Since optimization over the characteristic Cauchy problems is more justified from a theoretical perspective, one can interpret the indicated differences as error estimates for the other two approaches. It is seen that, near some of the points for which the value function is nonsmooth and the characteristic boundary value problem therefore admits multiple solutions, the values of $V_{MoC} - V_{MoC,BVP}$ are not negligible and are noticeably greater than the corresponding values of $|V_{MoC} - V_{FD}|$.

complexity has a strong impact on the practical implementation of related model predictive control schemes, where the optimal control action has to be recomputed at sampling instants using the available data on the current state (see, e.g., Wang 2009; Kang and Wilcox 2017) and the intervals between consecutive sampling instants are not large enough in comparison with the average time required for one control evaluation.

For certain classes of problems, sparse grid frameworks may help to attenuate the curse of

complexity if the state space dimension is moderate (typically not greater than 6) and if sparse grid interpolation is applied to functions with sufficiently smooth behavior (Kang and Wilcox 2017). In this case, the data on a sparse grid is generated offline (the possibility to independently treat different nodes on the sparse grid via a curse-of-dimensionality-free method allows the offline computation to be parallelized), and the online control evaluation for an arbitrary state in a certain bounded region is performed by

Characteristics in Optimal Control Computation, Fig. 2

Costate mapping between the direct Gauss pseudospectral discretization and Pontryagin's principle. This is a slight modification of Benson et al. (2006, Fig. 1)

using sparse grid interpolation. Note that interpolation of costates is preferable to that of feedback control strategies if the latter are expected to have a sharper behavior. Although the theoretical estimates for sparse grid interpolation errors are rather conservative and the actual errors may be very large, this approach could provide acceptable control performance for some practical models, as was demonstrated by Kang and Wilcox (2017).

Summary and Future Directions

In this entry, we briefly discussed some important characteristics-based approaches to approximating optimal open-loop control strategies and in particular how such indirect approaches may reasonably be combined with direct methods, as well as a possible transition to feedback control approximations via sparse grid techniques. To conclude, we point out some relevant directions of future research in related fields.

Kang and Wilcox (2017) used Smolyak's sparse grid constructions with hierarchical polynomial interpolation. Other methods of scattered data interpolation (e.g., Kriging) may be tested as well. In general, the range of applicability of such sparse grid frameworks to solving various feedback control problems is worth investigating.

It is also reasonable to use the discussed approaches for solving the exit-time optimal control problems that describe asymptotically stabilizing strategies (Michalska and Mayne 1993). Since the indirect (characteristics based) and direct collocation techniques enable costate estimation, it is relevant to design methods for constructing piecewise affine control Lyapunov functions in relatively high dimensions.

Another challenging direction is the development of curse-of-dimensionality-free approaches to solving HJI PDEs that arise in particular classes of zero-sum closed-loop two-player differential games; see, e.g., the related discussions in Yegorov and Dower (2018), Darbon and Osher (2016), and Chow et al. (2017). For general classes of nonlinear systems, this appears to be very difficult, due to potential singularities in the behavior of characteristics for zero-sum two-player differential games that include equivocal, envelope, and focal manifolds (Bernhard 1977; Melikyan 1998).

Abstract

The design of feedback control systems in industry is often carried out using frequency-response (FR) methods. Frequency-response design is used primarily because it provides good designs in the face of uncertainty in the plant model. For example, for systems with poorly known or changing high-frequency resonances, we can temper the feedback design to alleviate the effects of those uncertainties. This tempering can be carried out more easily using FR design without extensive modeling of the uncertainties. The method is most effective for systems that are stable in open loop; however, it can also be applied to systems

with instabilities. This article will introduce the reader to methods of design using lead and lag compensation. It will also cover the use of FR design to reduce steady-state errors and to improve robustness to uncertainties in high-frequency dynamics.

Keywords

Frequency response · Magnitude · Phase · Bode plot · Stability · Bandwidth · Disturbance rejection bandwidth · Phase margin · Gain margin · Crossover frequency · Notch filter · Gain stabilization · Amplitude stabilization

Introduction

Finding an appropriate compensation ($D(s)$ in Fig. 1) using frequency response is probably the easiest of all feedback control design methods. Designs are achievable starting with the frequency response (FR) plots of both magnitude and phase of $G(s)$, then selecting $D(s)$ to achieve certain values of the gain and/or phase margins and system bandwidth or error characteristics. This article will cover the design process for finding an appropriate $D(s)$.

Design Specifications

As discussed in the ► “Frequency-Response and Frequency-Domain Models”, the **gain margin (GM)** is the factor by which the gain can be raised before instability results. The **phase margin (PM)** is the amount by which the phase of $D(j\omega)G(j\omega)$ exceeds -180° when $|D(j\omega)G(j\omega)| = 1$, the **Crossover Frequency**. Performance requirements for control systems are often partially specified in terms of PM and/or GM. For example, a typical specification might include the requirement that $PM > 50^\circ$ and $GM > 5$. It can be shown that the PM tends to correlate well with the damping ratio, ζ , of the closed-loop roots. In fact, it is shown in Franklin et al. (2019) that

Classical Frequency-Domain Design Methods, Fig. 1 Feedback system showing compensation, $D(s)$, where R is the command input, U is the control, and Y is the plant output. (Source: Franklin, Powell, Emami-Naeini,

Feedback Control of Dynamic Systems, 8th Ed., © 2019, p-280, Reprinted by permission of Pearson Education, Inc., Upper Saddle River, NJ)

$$\zeta \cong \frac{PM}{100}$$

for many systems; however, the actual resulting damping and/or response overshoot of the final closed-loop system will need to be verified if they are specified as well as the PM. A PM of 50° would tend to yield a ζ of 0.5 for the closed-loop roots, which is a modestly damped system. The GM does not generally correlate directly with the damping ratio but is a measure of the degree of stability and is a useful secondary specification to ensure stability robustness.

Another design specification is the **bandwidth**, which is defined in the **Cross-Reference** section [1]. The bandwidth is a direct measure of the frequency at which the closed-loop system starts to fail in following the input command, responding with reduced magnitude and increasing phase lag. It is also a measure of the speed of response of a closed-loop system. Generally speaking, it correlates well with the step response and rise time of the system. A related design specification, the **disturbance rejection bandwidth**, also defined in the [► Frequency-Response and Frequency-Domain Models](#), evaluates the ability of the control system to reject disturbances. It signifies the upper limit of the disturbance frequency where the control system will reject its effect.

In some cases, the **steady-state error** must be less than a certain amount. As discussed in Franklin et al. (2019), the steady-state error is a direct function of the low-frequency gain of the FR magnitude plot. However, increasing the low-frequency gain typically will raise the entire mag-

nitude plot upward, thus increasing the magnitude 1 (0 db) crossover frequency and, therefore, increasing the speed of response, bandwidth, and disturbance rejection bandwidth of the system.

Compensation Design

In some cases, the design of a feedback compensation can be accomplished by using proportional control only, i.e., setting $D(s) = K$ (see Fig. 1) and selecting a suitable value for K . This can be accomplished by plotting the magnitude and phase of $G(s)$, looking at $|G(j\omega)|$ at the frequency where $\angle G(j\omega) = -180^\circ$ and then selecting K so that $|KG(j\omega)|$ yields the desired GM. Similarly, if a particular value of PM is desired, one can find the frequency where $\angle G(j\omega) = -180 + \text{the desired PM}$. The value of $|KG(j\omega)|$ at that frequency must equal 1; therefore, the value of $|G(j\omega)|$ must equal $1/K$. Note that the $|KG(j\omega)|$ curve moves vertically based on the value of K ; however the $\angle KG(j\omega)$ curve is not affected by the value of K . This characteristic simplifies the design process.

In more typical cases, proportional feedback alone is not sufficient. There is a need for a certain damping (i.e., PM) and/or speed of response (i.e., bandwidth), and there is no value of K that will meet the specifications. Therefore, some increased damping from the compensation is required. Likewise, a certain steady-state error requirement and its resulting low-frequency gain will cause the $|D(j\omega)G(j\omega)|$ to be greater than desired for an acceptable PM, so more phase lead is required from the compensation. This is

Classical Frequency-Domain Design Methods,

Fig. 2 Lead-compensation frequency response with $1/\alpha = 10$, $K = 1$. (Source: Franklin, Powell, Emami-Naeini, Feedback Control of Dynamic Systems, 8th Ed., © 2019, p-388 Reprinted by permission of Pearson Education, Inc.)

typically accomplished by **lead compensation**. A phase increase (or lead) is accomplished by placing a zero in $D(s)$. However, that alone would cause an undesirable high-frequency gain which would amplify noise; therefore, a first-order pole is added in the denominator at frequencies substantially higher than the zero break point of the compensator. Thus the phase lead still occurs, but the amplification at high frequencies is limited. The resulting lead compensation has a transfer function of the form

$$D(s) = K \frac{Ts + 1}{\alpha Ts + 1}, \quad \alpha < 1, \quad (1)$$

where $1/\alpha$ is the ratio between the pole/zero break-point frequencies. Figure 2 shows the frequency response of this lead compensation. The maximum amount of phase lead supplied is dependent on the ratio of the pole to zero and is shown in Fig. 3 as a function of that ratio.

For example, a lead compensator with a zero at $s = -2$ ($T = 0.5$) and a pole at $s = -10$ ($\alpha T = 0.1$) (and thus $\alpha = \frac{1}{5}$) would yield the maximum phase lead of $\phi_{\max} = 40^\circ$, where

$$\sin(\phi_{\max}) = \frac{1 - \alpha}{1 + \alpha}.$$

Classical Frequency-Domain Design Methods,

Fig. 3 Maximum phase increase for lead compensation. (Source: Franklin, Powell, Emami-Naeini, Feedback Control of Dynamic Systems, 8th Ed., © 2019, p-390, Reprinted by permission of Pearson Education, Inc.)

Note from the figure that we could increase the phase lead almost up to 90° using higher values of the **lead ratio**, $1/\alpha$; however, Fig. 2 shows that increasing values of $1/\alpha$ also produces higher amplifications at higher frequencies. Thus our task is to select a value of $1/\alpha$ that is a good compromise between an acceptable PM and acceptable noise sensitivity at high frequencies. Usually the compromise suggests that a lead compensation should contribute a maximum of 70° to the

phase. If a greater phase lead is needed, then a double-lead compensation would be suggested, where

$$D(s) = K \left(\frac{Ts + 1}{\alpha Ts + 1} \right)^2.$$

Even if a system had negligible amounts of noise present, the pole must exist at some point because of the impossibility of building a pure differentiator. No physical system—mechanical or electrical or digital—responds with infinite amplitude at infinite frequencies, so there will be a limit in the frequency range (or bandwidth) for which derivative information (or phase lead) can be provided.

As an example of designing a lead compensator, let us design compensation for a DC motor with the transfer function

$$G(s) = \frac{1}{s(s + 1)}.$$

We wish to obtain a steady-state error (e_{ss}) of less than 0.1 for a unit-ramp input, and we desire a system bandwidth greater than 3 rad/sec. Furthermore, we desire a PM of 45° . To accomplish the error requirement, Franklin et al., show that

$$e_{ss} = \lim_{s \rightarrow 0} s \left[\frac{1}{1 + D(s)G(s)} \right] R(s), \quad (2)$$

and if $R(s) = 1/s^2$ for a unit ramp, Eq. (2) reduces to

$$e_{ss} = \lim_{s \rightarrow 0} \left\{ \frac{1}{s + D(s)[1/(s + 1)]} \right\} = \frac{1}{D(0)}.$$

Therefore, we find that $D(0)$, the steady-state gain of the compensation, cannot be less than 10 if it is to meet the error criterion, so we pick $K = 10$. The frequency response of $KG(s)$ in Fig. 4 shows that the PM = 20° if no phase lead is added by compensation. If it were possible to simply add phase without affecting the magnitude, we would need an additional phase of only 25° at the $KG(s)$ crossover frequency of $\omega = 3$ rad/sec. However, maintaining the same low-frequency gain and adding a compensator zero will increase the crossover frequency;

hence more than a 25° phase contribution will be required from the lead compensation. To be safe, we will design the lead compensator so that it supplies a maximum phase lead of 40° . Figure 3 shows that $1/\alpha = 5$ will accomplish that goal. We will derive the greatest benefit from the compensation if the maximum phase lead from the compensator occurs at the crossover frequency. With some trial and error, we determine that placing the zero at $\omega = 2$ rad/sec and the pole at $\omega = 10$ rad/sec causes the maximum phase lead to be at the crossover frequency. The compensation, therefore, is

$$D(s) = 10 \frac{s/2 + 1}{s/10 + 1}.$$

The frequency-response characteristics of $L(s) = D(s)G(s)$ in Fig. 4 can be seen to yield a PM of 53° , which satisfies the PM and steady-state error design goals. In addition, the crossover frequency of 5 rad/sec will also yield a bandwidth greater than 3 rad/sec, as desired.

Lag compensation is the same form as the lead compensation in Eq. (1) except that $\alpha > 1$. Therefore, the pole is at a lower frequency than the zero, and it produces higher gain at lower frequencies. The compensation is used primarily to reduce steady-state errors by raising the low-frequency gain, but without increasing the crossover frequency and speed of response. This can be accomplished by placing the pole and zero of the lag compensation well below the crossover frequency. Alternatively, lag compensation can also be used to improve the PM by keeping the low frequency gain the same but reducing the gain near crossover, thus reducing the crossover frequency. That will usually improve the PM since the phase of the uncompensated system typically is higher at lower frequencies.

Systems being controlled often have high-frequency dynamic phenomena, such as mechanical resonances, that could have an impact on the stability of a system. In very-high-performance designs, these high-frequency dynamics are included in the plant model, and a compensator is designed with a specific knowledge of those dynamics. However, a more **robust** approach

Classical Frequency-Domain Design Methods,

Fig. 4 Frequency response for lead-compensation design. (Source: Franklin, Powell, Emami-Naeini, *Feedback Control of Dynamic Systems*, 8th Ed., © 2019, p-391, Reprinted by permission of Pearson Education, Inc.)

for designing with uncertain high-frequency dynamics is to keep the high-frequency gain low, just as we did for sensor-noise reduction. The reason for this can be seen from the gain-frequency relationship of a typical system, shown in Fig. 5. The only way instability can result from high-frequency dynamics is if an unknown high-frequency resonance causes the magnitude to rise above 1 (0 db). Conversely, if all unknown high-frequency phenomena are guaranteed to remain below a magnitude of 1 (0 db), stability can be guaranteed. The likelihood of an unknown resonance in the plant G rising above 1 (0 db) can be reduced if the nominal high-frequency loop gain (L) is lowered by the addition of extra poles

in $D(s)$, such as in a low-pass filter. When the stability of a system with resonances is assured by tailoring the high-frequency magnitude never to exceed 1 (0 db), we refer to this process as **amplitude** or **gain stabilization**. Of course, if the resonance characteristics are known exactly and remain the same under all conditions, a specially tailored compensation, such as a **notch filter** at the resonant frequency, can be used to tailor the phase for stability even though the amplitude does exceed magnitude 1 (0 db) as explained in Franklin et al. (2019). Design of a notch filter is more easily carried out using **root locus** or **state space** design methods, all of which are discussed in Franklin et al. (2019). This

Classical Frequency-Domain Design Methods,
Fig. 5 Effect of high-frequency plant uncertainty.
 (Source: Franklin, Powell, Emami-Naeini, Feedback
 Control of Dynamic Systems, 8th Ed., © 2019, p-412,
 Reprinted by permission of Pearson Education, Inc.)

method of stabilization is referred to as **phase stabilization**. A drawback to phase stabilization is that the resonance information is often not available with adequate precision or varies with time; therefore, the method is more susceptible to errors in the plant model used in the design. Thus, we see that sensitivity to plant uncertainty and sensor noise are both reduced by sufficiently low gain at high frequency.

Summary and Future Directions

Before the common use of computers in design, frequency-response design was the most widely used method. While it is still the most widely used method for routine designs, complex systems, and their designs are being carried out using a multitude of methods. This section has introduced the classical methods used before and after the widespread use of computers in design. Future designs in the frequency domain will most likely capitalize on the capability of computers to balance many objectives in design by the optimization of various cost functions. This approach is discussed in ► [Control System Optimization Methods in the Frequency Domain](#)

Computational Complexity in Robustness Analysis and Design

Onur Toker

Electrical and Computer Engineering, Florida Polytechnic University, Lakeland, FL, USA

Abstract

For many engineering analysis and design problems, one can think about various different types of algorithms with quite different features. Depending on the specific application, “general”, “practical”, and even “optimal” may have different meanings. In this chapter, we will be following the standards defined in the theory of computation, (Garey, Johnson (1979) Computers and intractability, a guide to the theory of NP-completeness. W. H. Freeman, San Francisco; Papadimitriou (1995) Computational complexity. Addison-Wesley/Longman, Reading), but we also would like to present an engineering interpretation of these concepts. First of all, an algorithm is considered as

“general”, if it really provides a correct answer for all cases of the problem. Although this makes perfect sense from a scientific perspective, it may be too restrictive from an engineering/economical viewpoint. For example, a technique which can be used for most cases may also be considered as “general” enough. An algorithm is considered as “practical” if its execution time is reasonable. From a scientific perspective, the worst case execution time looks more appealing, but for many engineering projects average execution time may be more meaningful. Similarly, there is no universal definition for reasonable execution time, but most scientists and engineers agree that polynomial execution time is reasonable, and anything beyond that is not. In this entry, we will look at some of the classical robust control problems, and try to present an engineering interpretation of the relevant computational complexity results.

Keywords

Approximation complexity · Computational complexity · *NP*-complete · *NP*-hard · Unsolvability

Introduction

Engineering literature is full of complex and challenging analysis and design problems, and we are usually interested in finding general, practical, and optimal solution techniques. Some of these are decision problems where the answer is either YES or NO, but there are also more involved design problems where the output of the procedure is expected to be something more complicated than a simple Boolean value. Therefore, we need to clarify what is an algorithm and provide a rigorous definition consistent with our intuitive understanding. Although the theory of computation provides mathematically rigorous definitions for a computer, and an algorithm, we may still have disagreements on certain details, for example, whether probabilistic methods should

be allowed or not. To find a primitive root in $\mathbb{Z}_p$ (Knuth 1997), there are highly effective techniques which involve random number generation. One may ask whether a random number generation-based set of rules should also be considered as an algorithm, provided that it will terminate almost surely after a few number of steps for all instances of the problem. In a similar fashion, one may ask whether any real number should be allowed as an input to an algorithm. Furthermore, one may also ask whether all calculations should be limited to algebraic functions only or should exact calculation of a limited set of non-algebraic functions, e.g., trigonometric functions, the gamma function, etc. should be considered as acceptable in an algorithm. Although all of these look reasonable options, from a rigorous point of view, they are different notions. In the following, we will be adopting the standard definitions of the theory of computation.

Turing Machines

Alan M. Turing (Turing 1936) defined a “hypothetical computation machine” to formally define the notions of algorithm and computability. A Turing machine is, in principle, quite similar to today’s digital computers. An algorithm is a Turing machine with a program, which is guaranteed to terminate after finitely many steps. These are basically standard definitions in the theory of computation, but alternative more relaxed definitions are possible too.

Depending on new scientific, engineering, and technological developments, superior computation machines may be constructed. For example, there is no guarantee that quantum computing research will not lead to superior computation machines (Chen et al. 2006; Kaye et al. 2007). In the future, the engineering community may feel the need to revise formal definitions of computer, algorithm, computability, tractability, etc., if such superior computation machines can be constructed and used for scientific/engineering applications.

Mathematical definition and basic properties of Turing machines are discussed in Garey and Johnson (1979), Papadimitriou (1995),

Hopcroft et al. (2001), Lewis and Papadimitriou (1998) and Sipser (2006). Although the original mathematical definition refers to a quite simple and low-performance “hardware” compared to today’s much higher-performance devices, the following two observations justify their use in the study of computational complexity of engineering problems. Anything which can be solved on today’s current digital computers can be solved on a Turing machine. Furthermore, a polynomial-time algorithm on today’s digital computers will correspond to again a polynomial-time algorithm on the original Turing machine, and vice versa.

When we use the term polynomial-time, we indeed mean polynomial-time in problem size. The notion of “problem size” is an important detail. For example, consider the problem of deciding whether an $n \times n$ matrix is singular or not. What is the most natural or meaningful definition for the problem size? If we decide to use IEEE floating formats, and simply ignore round of errors, problem size can be defined as n . But from a scientific perspective, ignoring these round of errors may not be acceptable, and we may be forced to define the problem size as the total number of bits required to represent the input. No matter which encoding is used, there will be always numbers which cannot be represented precisely, and in that case, because of being unable to present the input to the computer, we may not even talk about solution algorithms. A more interesting case is a 2×2 matrix with entries requiring very large number of bits to encode. In that case, the theory of computation suggests a large value for the problem size, which may or may not be acceptable from an engineering perspective. Although the whole theory is based on rigorous mathematical definitions and theories, sometimes certain definitions may look a bit counterintuitive. Knowing all of these details is essential for proper interpretation of the computational complexity results.

Unsolvability

For certain engineering problems, it can be shown that there can be no algorithm which can provide the correct answer for all possible cases. Such

problems are called unsolvable. The condition “all cases” may be considered as too restrictive from an engineering perspective, and one may argue that such negative results have only theoretical importance with limited or no practical implications. But such results do imply that we should concentrate our efforts on alternative research directions, for example, development of algorithms which are guaranteed to work for cases which appear more frequently in real scientific/engineering applications.

Hilbert’s tenth problem is basically about finding an algorithm for testing whether a Diophantine equation has an integer solution. In 1970, Matijasevich showed that there can be no algorithm (Matijasevich 1993) which can handle all possible cases. Therefore, we say that the problem of checking whether a Diophantine equation has an integer solution is unsolvable. For certain special cases, solution algorithms do exist, but unfortunately none of these can be extended to a general algorithm.

In robust control theory, there are certain unsolvable decision problems for systems with time-varying parametric uncertainty. Most of these can be reduced to what is known as the Post correspondence problem (Davis 1985) and the embedding of free semigroups into matrices. In (Blondel and Tsitsiklis 2000a), it was proved that the problem of checking the boundedness of switching systems of type

$$x(k+1) = A_{f(k)}x(k),$$

where f is an arbitrary unknown function from $\mathbb{N}$ into $\{0, 1\}$, is unsolvable. This is related to a time-varying parametric uncertainty problem with system dynamics described by

$$x(k+1) = (c_k A_0 + (1 - c_k) A_1)x(k), \quad (1)$$

with c_k being the time-varying uncertain parameter in $[0, 1]$, and we are only interested in boundedness of the state vector. Stated in a more formal way:

Bounded state for time-varying parametric uncertainty problem (BSTVP) Consider the

dynamical system defined in (1) with the time-varying uncertain parameter c_k in $[0, 1]$. The problem is to test whether the state vector x remains bounded.

Results proved in Blondel and Tsitsiklis (2000a) imply that the BSTVP is an unsolvable problem. A related problem is asymptotic stability against time-varying parametric uncertainty, more precisely whether the state vector converges to zero.

Asymptotic stability for time-varying parametric uncertainty problem (ASTVP) Consider the dynamical system defined in (1) with the time-varying uncertain parameter c_k in $[0, 1]$. The problem is to test whether the state vector x converges to zero, i.e., checking whether $\lim_{k \rightarrow \infty} \|x(k)\| = 0$.

This is known to be related to the joint spectral radius (JSR) (Rota and Strang 1960), indeed equivalent to whether the JSR of $\{A_0, A_1\}$ is less than one. In other words, checking whether JSR is less than one is a kind of robust stability test against time-varying parametric uncertainty. For a long period of time, a simple procedure based on what is known as the finiteness conjecture (FC) (Lagarias and Wang 1995) was considered as an algorithm candidate for testing robust stability. Till the 2000s, there was no known counter example for the finiteness conjecture, and a significant number of scientists and engineers considered it as true. FC may be interpreted as “For asymptotic stability of $x(k+1) = A_{f(k)}x(k)$ type switching systems, it is enough to consider periodic switchings.” The truth of this FC conjecture would imply existence of an algorithm for the ASTVP problem. However, it was shown in Bousch and Mairesse (2002) that FC is not true (see Blondel et al. (2003) for a significantly simplified proof). To the best of the author’s knowledge, whether ASTVP is solvable or not is an open problem. However, there are several very useful results about computing and/or approximating the joint spectral radius. See Blondel and Nesterov (2005, 2009), Protasov et al. (2010), and Chang and Blondel (2013) and references therein for details. Despite all of these strong results, existence of an algorithm to test whether

JSR is less than one remains as an open problem. For further results on unsolvability in robust control, see Blondel et al. (1999) and Blondel and Megretski (2004) and references therein.

NP-Hardness and NP-Completeness

Solvability of an engineering problem, more precisely a decision problem, is related to whether there exists an algorithm which is guaranteed to terminate in a finite amount of time. But the execution time of the algorithm is as important as its existence. Consider a graph theoretic problem, let n be the number of nodes, and consider an algorithm which requires 2^n steps on a Turing machine or a digital computer. Such algorithms with execution times growing faster than polynomial are considered as inefficient. On the other hand, algorithms with worst-case execution times bounded by a polynomial of the problem size are considered as efficient.

One may argue that bounding the worst-case execution time by a polynomial of the problem size may be too restrictive for certain applications. Indeed, depending on the nature of the specific application, being polynomial-time on the average may be good enough. The same may be true for algorithms which are polynomial-time almost surely, or for “most” of the cases. However, the standard computational complexity theory is developed around this idea of being polynomial-time even in the worst case (Garey and Johnson 1979; Papadimitriou 1995). Understanding this detail is also essential for proper interpretation of complexity results.

To explain NP-hardness, NP-completeness, and tractability, we need to define certain sets. The class P corresponds to decision problems which can be solved on a Turing machine with execution time bounded by a polynomial of the problem size (Garey and Johnson 1979). In short, such problems are categorized as decision problems which have polynomial-time solution algorithms. The definition of the class NP is more technical and involves nondeterministic Turing machines (Garey and Johnson 1979). Nondeterministic Turing machines can be considered as computers executing one of the

finitely many instructions on a random basis. The class NP may also be interpreted as the class of decision problems for which the truth of the problem can be verified in polynomial-time. Nondeterministic Turing machines may not have a major practical use, but they are quite important from a theoretical perspective.

It is currently unknown whether P and NP are equal or not. This is a major open problem, and the importance of it in the theory of computation is comparable to the importance of the Riemann hypothesis in number theory. Indeed both are among unsolved Millennium Prize Problems.

A problem is NP -complete if it is NP and every NP problem polynomially reduces to it (Garey and Johnson 1979). When a problem is proved to be NP -complete, it means that finding a polynomial-time solution algorithm is not possible, provided $P \neq NP$. There are several NP -complete problems for which there is no known polynomial-time algorithm. Despite significant amount of research, there is no known polynomial-time algorithm for any of the NP -complete problems. This *may* be considered as indication of $NP \not\subseteq P$. Indeed, finding a polynomial-time solution algorithm for any of the NP -complete problems will automatically imply existence of polynomial-time solution algorithms for all NP -complete problems, and this will be a major breakthrough if it is indeed true. Although current evidence is more toward $P \neq NP$, this does not constitute a formal proof.

Being NP -complete is considered as being intractable, and this whole argument may collapse if P and NP turns out to be equal. However, under the assumption of $NP \not\subseteq P$, a problem being NP -complete does imply impossibility of finding polynomial-time solution algorithms. Again, the standard theory of computation requires algorithms to handle *all* cases properly, execution time to be *always* bounded by a polynomial of the problem size, and the definition of problem size may look a bit counterintuitive in certain cases. These details and assumptions are important for proper interpretation of the complexity results.

A problem is called NP -hard if and only if there is an NP -complete problem which is

polynomial-time reducible to it (Garey and Johnson 1979). Being NP -hard is also considered as being intractable, because unless $P = NP$, no polynomial-time solution algorithm can be found. All NP -complete problems are also NP -hard.

Approximation-Based Techniques

NP -hardness and NP -completeness are originally defined to express the inherent difficulty of decision-type problems. But there are several very important engineering problems which are of approximation type; see Papadimitriou (1995). Most of the robust stability tests can be formulated as “Check whether $\gamma < 1$,” which is basically a decision-type problem. An approximate value of γ may not be always good enough to “solve” the problem. For a robust stability analysis problem, a result like $\gamma = 0.99 \pm 0.02$ may be not enough to decide about robust stability, although the approximation error is about 2% only. However, for certain other engineering applications, including robustness margin estimation, approximate values may be good enough. Namely, from an engineering perspective, a good enough approximation of γ may be as good as the exact value. Exact version may be NP -hard, but this does not necessarily imply that the approximation version will be NP -hard too. If the exact version is not tractable, and the approximation version makes sense from an engineering perspective, it may be worth to consider the approximation version and try to find algorithms for this relaxed version.

Basic Results

The first known NP -complete problem is SATISFIABILITY (Cook 1971). In this problem, there is a single Boolean equation with several variables, and we would like to test whether there exists an assignment to these variables which makes the Boolean expression true. NP -completeness of SATISFIABILITY enabled proofs of several other NP -completeness results from graph theory to quadratic optimization.

Quadratic programming is an important problem by itself, but it is also related several important robust stability against parametric

uncertainty-type problems. The quadratic programming (QP) can be defined as

$$q = \min_{Ax \leq b} x^T Qx + c^T x,$$

and the decision version is checking whether $q < 1$. When the matrix Q is positive definite, convex optimization techniques can be used; however, if the matrix Q is not positive definite, then the problem is known to be *NP*-hard.

A related problem is linear programming (LP)

$$q = \min_{Ax \leq b} c^T x,$$

which is used in certain robust control problems (Dahleh and Diaz-Bobillo 1994). The simplex method (Dantzig 1963) is a well-known computational technique for linear programming, and it has polynomial-time complexity on the “average” (Smale 1983). However, there are examples where the simplex method requires execution time which is an exponential function of the problem size (Klee and Minty 1972). In 1979, Khachiyan proposed the ellipsoid algorithm for linear programming, which was the first known polynomial-time approximation algorithm (Schrijver 1998) for linear programming. It is possible to answer the decision version, i.e., checking whether q is less than 1, in polynomial-time too. This is possible by using the ellipsoid algorithm for approximation and stopping when the error is below a certain level. But all of these results are for standard Turing machines with input parameters restricted to rational numbers. An interesting open problem is whether LP admits a polynomial-time algorithm in the real number model of computation.

Decision version of QP is *NP*-hard, but approximation of QP is quite “difficult” as well. An approximation is called a μ -approximation if the absolute value of the error is bounded by μ times the absolute value of max-min of the function. The following is a classical result on QP (Bellare and Rogaway 1995): Unless $P = NP$, QP does not admit a polynomial-time μ -approximation algorithm even for $\mu < 1/3$.

This is sometimes informally stated as “QP is *NP*-hard to approximate.”

Computational Complexity of Robust Control Problems

Our discussion of computational complexity in robust control will be limited to interval matrices, time-invariant parametric uncertainty, and the structured singular value. For other robust control problems, please see Blondel and Tsitsiklis (2000b), Blondel et al. (1999), Blondel and Megretski (2004), and references therein.

Kharitonov theorem is about robust Hurwitz stability of polynomials with coefficients restricted to intervals (Kharitonov 1978). In its original formulation, each coefficient is considered as a separate time-invariant uncertain parameter. This version of the problem has a very simple and elegant solution (see Cross-References). If algebraic dependencies between coefficients are allowed, then the problem will be *NP*-hard. To understand why, we need to look at interval matrix problem. A set of matrices defined by the equation,

$$\mathcal{A} = \{A \in \mathbb{R}^{n \times n} : \alpha_{i,j} \leq A_{i,j} \leq \beta_{i,j}, \\ i, j = 1, \dots, n\}, \quad (2)$$

where $\alpha_{i,j}, \beta_{i,j} \in \mathbb{R}$ for $i, j = 1, \dots, n$, is called an interval matrix. Consider the mathematical model of a complex system with multiple physical parameters. If we have only partial information about each physical parameter, then it may be possible to represent system dynamics as

$$\dot{x} = Mx + Bu$$

where M is some unknown but fixed matrix in an interval matrix $\mathcal{A}$. In this case, robust stability will be equivalent to Hurwitz stability of all matrices in $\mathcal{A}$. The following two stability problems about interval matrices are *NP*-hard:

Interval Matrix Problem 1 (IMP1): Decide whether a given interval matrix, $\mathcal{A}$, is robust Hurwitz stable or not. Namely, check whether all members of $\mathcal{A}$ are Hurwitz-stable matrices, i.e., all eigenvalues are in open left half plane.

Interval Matrix Problem 2 (IMP2): Decide whether a given interval matrix, $\mathcal{A}$, has a Hurwitz-stable matrix or not. Namely, check whether there exists at least one matrix in $\mathcal{A}$ which is Hurwitz stable.

For a proof of NP -hardness of IMP1, see Poljak and Rohn (1993) and Nemirovskii (1993), and for a proof of IMP2, see Blondel and Tsitsiklis (1997).

For interconnected systems with component-level uncertainties (Packard and Doyle 1993), robust stability can be checked by using structured singular values. Basically, if we do know bounds on the component-level uncertainties, robust stability can be tested by checking whether a structured singular value is less than 1 or not. However, this problem is known to be NP -hard.

Structured Singular Value Problem (SSVP):

Given a matrix M and uncertainty structure Δ , check whether the structured singular value $\mu_{\Delta}(M) < 1$.

This is proved to be NP -hard for real, and mixed, uncertainty structures (Braatz et al. 1994), as well as for complex uncertainties with no repetitions (Toker and Ozbay 1996, 1998).

Complex structured singular problem value has a simpler convex relaxation. This is known as the standard upper bound $\bar{\mu}$, which is known to give quite tight approximations for most cases (Packard and Doyle 1993). But there are very limited results about $\bar{\mu}/\mu$ ratio.

Summary and Future Directions

For all of the NP -completeness and NP -hardness results presented here, to be able to say that there is no polynomial-time algorithm, we need the assumption “ $P \neq NP$ ”, which is not proved yet. That’s why this is a central question in the theory of computation. Researchers agree that really new and innovative tools are needed to study this problem. On one other extreme, one can question whether we can really say something about this problem within the Zermelo-Fraenkel (ZF) set theory or it will have a status similar to axiom

of choice (AC) and the continuum hypothesis (CH) where we can neither refute nor provide a proof (Aaronson 1995). Therefore, the question may be indeed much deeper, and standard axioms of today’s mathematics may not be enough to provide an answer. As for any such problem, we can still hope that in the future, new “self-evident” axioms may be discovered, and with the help of them, we may provide an answer.

All of the complexity results mentioned here are with respect to the standard Turing machine which is a simplified model of today’s digital computers. Depending on the progress in science, engineering, and technology, if superior computation machines can be constructed, then some of the abovementioned problems can be solved much faster on these devices, and current results/problems of the theory of computation may no longer be of great importance or relevance for engineering and scientific applications. In such a case, definitions of algorithm, tractable, etc. may need to be revised according to these new devices.

For NP -hard robust control problems, various relaxations may be considered. For example, approximation with a bounded error may be one alternative. Similarly, algorithms which are polynomial-time on the average or polynomial-time for most of cases can be considered as potential alternatives. In summary, computational complexity theory guides research on the development of algorithms, indicating which directions are dead ends and which directions are worth to investigate. Complete understanding of the basic concepts of the theory of computation is very important for a proper engineering interpretation of these complexity results.

Computer-Aided Control Systems Design: Introduction and Historical Overview

Andreas Varga
Gilching, Germany

Abstract

Computer-aided control system design (CACSD) encompasses a broad range of methods, tools, and technologies for system modelling, control system synthesis and tuning, dynamic system analysis and simulation, as well as validation and verification. The domain of CACSD enlarged progressively over decades from simple collections of algorithms and programs for control system analysis and synthesis to comprehensive tool sets and user-friendly environments supporting all aspects of developing and deploying advanced control systems in various application fields. This entry gives a brief introduction to CACSD and reviews the evolution of key concepts and technologies underlying the CACSD domain. Several cornerstone achievements in developing reliable numerical algorithms; implementing robust numerical software; and developing sophisticated integrated modelling, simulation, and design environments are highlighted.

Keywords

CACSD · Modelling · Numerical analysis · Simulation · Software tools

Introduction

To design a control system for a plant, a typical *computer-aided control system design* (CACSD) work flow comprises several interlaced activities.

Model building is often a necessary first step consisting in developing suitable mathematical models to accurately describe the

plant dynamical behavior. High-fidelity physical plant models obtained, for example, by using the first principles of modelling, primarily serve for analysis and validation purposes using appropriate simulation techniques. These dynamic models are usually defined by a set of *ordinary differential equations* (ODEs), *differential-algebraic equations* (DAEs), or *partial differential equations* (PDEs). However, for control system synthesis purposes, simpler models are required, which are derived by simplifying high-fidelity models (e.g., by linearization, discretization, or model reduction) or directly determined in a specific form from input-output measurement data using system identification techniques. Frequently used synthesis models are continuous or discrete-time *linear time-invariant* (LTI) models describing the nominal behavior of the plant in a specific operating point. The more accurate *linear parameter-varying* (LPV) models may serve to account for uncertainties due to various performed approximations, nonlinearities, or varying model parameters.

Simulation of dynamical systems is a closely related activity to modelling and is concerned with performing virtual experiments on a given plant model to analyze and predict the dynamic behavior of a physical plant. Often, modelling and simulation are closely connected parts of dedicated environments, where specific classes of models can be built and appropriate simulation methods can be employed. Simulation is also a powerful tool for the validation of mathematical models and their approximations. In the context of CACSD, simulation is frequently used as a control system tuning-aid, as, for example, in an optimization-based tuning approach using time-domain performance criteria.

System analysis and synthesis are concerned with the investigation of properties of the underlying synthesis model and the determination of a control system which fulfills basic requirements for the closed-loop controlled plant, such as stability or various time or frequency response requirements. The analysis also serves to check existence conditions for the solvability of synthesis problems, according to established design

methodologies. An important synthesis goal is the guarantee of the performance robustness. To achieve this goal, robust control synthesis methodologies often employ optimization-based parameter tuning in conjunction with worst-case analysis techniques. A rich collection of reliable numerical algorithms are available to perform such analysis and synthesis tasks. These algorithms form the core of CACSD, and their development represented one of the main motivations for CACSD-related research.

Performance robustness assessment of the resulting closed-loop control system is a key aspect of the verification and validation activity. For a reliable assessment, simulation-based worst-case analysis represents, often, the only way to prove the performance robustness of the synthesized control system in the presence of parametric uncertainties and variabilities.

Development of CACSD Tools

The development of CACSD tools for system analysis and synthesis started around 1960, immediately after general-purpose digital computers, and new programming languages became available for research and development purposes. In what follows, we give a historical survey of these developments in the main CACSD areas.

Modelling and Simulation Tools

Among the first developments were modelling and simulation tools for continuous-time systems described by differential equations based on dedicated simulation languages. Over 40 continuous system simulation languages had been developed as of 1974 (Nilsen and Karplus 1974), which evolved out of attempts at digitally emulating the behavior of widely used analog computers before 1960. A notable development in this period was the Continuous System Simulation Language (CSSL) standard (Augustin et al. 1967), which defined a system as an interconnection of blocks corresponding to operators which emulated the main analog simulation blocks and implied the integration of the underlying ODEs using suitable numerical

methods. For many years, the Advanced Continuous Simulation Language (ACSL) preprocessor to Fortran (Mitchel and Gauthier 1976) was one of the most successful implementations of the CSSL standard.

A turning point was the development of graphical user interfaces allowing graphical block diagram-based modelling. The most important developments were SystemBuild (Shah et al. 1985) and SIMULAB (later marketed as Simulink) (Grace 1991). Both products used a customizable set of block libraries and were seamlessly integrated in, respectively, MATRIXx and MATLAB, two powerful interactive matrix computation environments (see below). SystemBuild provided several advanced features such as event management, code generation, and DAE-based modelling and simulation. Simulink excelled from the beginning with its intuitive, easy-to-use user interface. Recent extensions of Simulink allow the modelling and simulation of hybrid systems, code generation for real-time applications, and various enhancements of the model building process (e.g., object-oriented modelling).

The object-oriented paradigm for system modelling was introduced with Dymola (Elmqvist 1978) to support physical system modelling based on interconnections of subsystems. The underlying modelling language served as the basis of the first version of Modelica (Elmqvist et al. 1997), a modern equation-based modelling language which was the result of a coordinated effort for the unification and standardization of expertise gained over many years with object-oriented physical modelling. The latest developments in this area are comprehensive model libraries for different application domains such as mechanical, electrical, electronic, hydraulic, thermal, control, and electric power systems. Notable commercial front ends for Modelica are Dymola, MapleSim, and System-Modeler, where the last two are tightly integrated in the symbolic computation environments Maple and Mathematica, respectively. Recent efforts toward extending the capabilities of Modelica, by simultaneously simplifying the modelling effort and enlarging its application area, are described

in Elmqvist et al. (2016), where the design of a new modelling language, called Modia, is presented. Modia is based on the Julia language (Bezanson et al. 2017) and relies on powerful DAE solvers.

Numerical Software Tools

The computational tools for CACSD rely on many numerical algorithms whose development and implementation in computer codes was the primary motivation of this research area since its beginnings. The Automatic Synthesis Program (ASP), developed in 1966 (Kalman and Englar 1966), was implemented in FAP (Fortran Assembly Program) and ran only on an IBM 7090–7094 machine. The Fortran II version of ASP (known as FASP) can be considered to be the first collection of computational CACSD tools ported to several mainframe computers. Interestingly, the linear algebra computations were covered by only three routines (diagonal decomposition, inversion, and pseudoinverse), and no routines were used for eigenvalue or polynomial roots computation. The main analysis and synthesis functions covered the sampled-data discretization (via matrix exponential), minimal realization, time-varying Riccati equation solution for quadratic control, filtering, and stability analysis. The FASP itself performed the required computational sequences by interpreting simple commands with parameters. The extensive documentation, containing a detailed description of algorithmic approaches and many examples, marked the starting point of an intensive research on algorithms and numerical software, which culminated in the development of the high-performance control and systems library SLICOT (Benner et al. 1999; Van Huffel et al. 2004). In what follows, we highlight the main achievements along this development process.

The direct successor of FASP is the Variable Dimension Automatic Synthesis Program (VASP) (implemented in Fortran IV on IBM 360) (White and Lee 1971), while a further development was ORACLS (Armstrong 1978), which included several routines from the newly developed eigenvalue package EISPACK (Smith et al. 1976; Garbow et al. 1977) as well as

solvers for linear (Lyapunov, Sylvester) and quadratic (Riccati) matrix equations. From this point, the mainstream development of numerical algorithms for linear system analysis and synthesis closely followed the development of algorithms and software for numerical linear algebra. A common feature of all subsequent developments was the extensive use of robust linear algebra software with the Basic Linear Algebra Subprograms (BLAS) (Lawson et al. 1979) and the Linear System Package (LINPACK) for solving linear systems (Dongarra et al. 1979). Several control libraries have been developed almost simultaneously, relying on the robust numerical linear algebra core software formed of BLAS, LINPACK, and EISPACK. Notable examples are RASP (based partly on VASP and ORACLS) (Grübel 1983) – developed originally by the University of Bochum and later by the German Aerospace Center (DLR); BIMAS (Varga and Sima 1985) and BIMASC (Varga and Davidoviciu 1986) – two Romanian initiatives; and SLICOT (van den Boom et al. 1991) – a Benelux initiative of several universities jointly with the Numerical Algorithms Group (NAG).

The last development phase was marked by the availability of the Linear Algebra Package (LAPACK) (Anderson et al. 1992), whose declared goal was to make the widely used EISPACK and LINPACK libraries run efficiently on shared memory vector and parallel processors. To minimize the development efforts, several active research teams from Europe started, in the framework of the NICONET project, a concentrated effort to develop a high-performance numerical software library for CACSD as a new significantly extended version of the original SLICOT. The goals of the new library were to cover the main computational needs of CACSD, by relying exclusively on LAPACK and BLAS, and to guarantee similar numerical performance as that of the LAPACK routines. The software development used rigorous standards for implementation in Fortran 77, modularization, testing, and documentation (similar to that used in LAPACK). The development of the latest versions of RASP and SLICOT eliminated practically any duplication of efforts and led to

a library which contained the best software from RASP, SLICOT, BIMAS, and BIMASC. The current version of SLICOT is fully maintained by the NICONET association (<http://www.niconet-ev.info/en/>) and serves as basis for implementing advanced computational functions for CACSD in interactive environments such as MATLAB (<https://www.mathworks.com>), Maple (<https://www.maplesoft.com/products/maple/>), Scilab (<https://www.scilab.org/>), and Octave (<https://www.gnu.org/software/octave/>).

Interactive Tools

Early experiments during 1970–1985 included the development of several interactive CACSD tools employing menu-driven interaction, question-answer dialogues, or command languages. The April 1982 special issue of IEEE Control Systems Magazine was dedicated to CACSD environments and presented software summaries of 20 interactive CACSD packages. This development period was marked by the establishment of new standards for programming languages (Fortran 77, C), availability of high-quality numerical software libraries (BLAS, EISPACK, LINPACK, ODEPACK), transition from mainframe computers to minicomputers, and finally to the nowadays-ubiquitous personal computers as computing platforms, spectacular developments in graphical display technologies, and application of sound programming paradigms (e.g., strong data typing).

A remarkable event in this period was the development of MATLAB, a command language-based interactive matrix laboratory (Moler 1980). The original version of MATLAB was written in Fortran 77. It was primarily intended as a student teaching tool and provided interactive access to selected subroutines from LINPACK and EISPACK. The tool circulated for a while in the public domain, and its high flexibility was soon recognized. Several CACSD-oriented commercial clones have been implemented in the C language, the most important among them being MATRIXx (Walker et al. 1982) and PC-MATLAB (Moler et al. 1985).

The period after 1985 until around 2000 can be seen as a consolidation and expansion period for

many commercial and noncommercial tools. In an inventory of CACSD-related software issued by the Benelux Working Group on Software (WGS) under the auspices of the IEEE Control Systems Society, there were in 1992 in active development 70 stand-alone CACSD packages, 21 tools based on or similar to MATLAB, and 27 modelling/simulation environments. It is interesting to look more closely at the evolutions of the two main players MATRIXx and MATLAB, which took place under harshly competitive conditions.

MATRIXx with its main components Xmath, SystemBuild, and AutoCode had over many years a leading role (especially among industrial customers), excelling with a rich functionality in domains such as system identification, control system synthesis, model reduction, modelling, simulation, and code generation. After 2003, MATRIXx (<https://www.ni.com/matrixx/>) became a product of the National Instruments Corporation and complements its main product family LabVIEW, a visual programming language-based system design platform and development environment (<https://www.ni.com/labview>).

MATLAB gained broad academic acceptance by integrating many new methodological developments in the control field into several control-related toolboxes. MATLAB also evolved as a powerful programming language, which allows easy object-oriented manipulation of different system descriptions via operator overloading. At present, the CACSD tools of MATLAB and Simulink represent the industrial and academic standard for CACSD. The existing CACSD tools are constantly extended and enriched with new model classes, new computational algorithms (e.g., structure-exploiting computations based on SLICOT), dedicated graphical user interfaces (e.g., tuning of PID controllers or control-related visualizations), advanced robust control system synthesis, etc. Also, many third-party toolboxes contribute to the wide usage of this tool.

Basic CACSD functionality incorporating symbolic processing techniques and higher-precision computations is available in the Maple product MapleSim Control Design Toolbox as

well as in the Mathematica Control Systems product. Free alternatives to MATLAB are the MATLAB-like environments Scilab, a French initiative pioneered by INRIA, and Octave, whose CACSD functionality strongly relies on SLICOT (see <https://octave.sourceforge.io/control/>).

Summary and Future Directions

The development and maintenance of integrated CACSD environments, which provide support for all aspects of the CACSD cycle such as modelling, design, and simulation, involve sustained, strongly interdisciplinary efforts. Therefore, the CACSD tool development activities must rely on the expertise of many professionals covering such diverse fields as control system engineering, programming languages and techniques, man-machine interaction, numerical methods in linear algebra and control, optimization, computer visualization, and model building techniques. This may explain why currently only a few of the commercial developments of prior years are still in use and actively maintained/developed. Unfortunately, the number of actively developed noncommercial alternative products is even lower. The dominance of MATLAB, as a de facto standard for both industrial and academic usage of integrated tools covering all aspects of the broader area of *computer-aided control engineering* (CACE), cannot be overlooked.

The new trends in CACSD are partly related to handling more complex applications, involving time-varying (e.g., periodic, multi-rate sampled-data, and differential algebraic) linear dynamic systems, nonlinear systems with many parametric uncertainties, and large-scale models (e.g., originating from the discretization of PDEs). To address many computational aspects of model building (e.g., model reduction of large order systems), optimization-based robust controller tuning using multiple-model approaches, or optimization-based robustness assessment using global-optimization techniques,

parallel computation techniques allow substantial savings in computational times and facilitate addressing computational problems for large-scale systems. A topic which needs further research is the exploitation of the benefits of combining numerical and symbolic computations (e.g., in model building and manipulation).

A promising new development for the future of CACSD is Julia, a powerful and flexible dynamic language, suitable for scientific and numerical computing, with performance comparable to traditional statically typed languages such as Fortran or C (see <https://julialang.org/>). As a programming language, Julia features optional typing, multiple dispatch, and good performance, achieved using type inference and just-in-time compilation (Bezanson et al. 2017). Julia is the basis of the implementation of the next-generation modelling language Modia (Elmqvist et al. 2016). CACSD-related functionality is provided in the Julia packages `ControlSystems` (<https://github.com/JuliaControl/ControlSystems.jl>) and `MatrixEquations` (<https://github.com/andreasvarga/MatrixEquations.jl>).

Conditioning of Quantum Open Systems

John Gough
Department of Physics, Aberystwyth University,
Aberystwyth, Wales, UK

Abstract

The underlying probabilistic theory for quantum mechanics is non-Kolmogorovian. The time-order in which physical observables are measured will be important if they are incompatible (non-commuting). In particular, the notion of conditioning needs to be handled with care and may not even exist in some cases. Here we layout the quantum probabilistic formulation in terms of von Neumann algebras and outline conditions (non-demolition properties) under which filtering may occur.

Keywords

Quantum filter · von Neumann algebra ·
Quantum probability · Bell's theorem

Introduction

The mathematical theory of quantum probability (QP) is an extension of the usual Kolmogorov probability to the setting inspired by quantum theory (Maassen 1988; Accardi et al. 1982; Hudson and Parthasarathy 1984; Parthasarathy 1992). In this entry, we will emphasize the quantum analogues to events (projections), random variables (operators), sigma-algebras (von Neumann algebras), probabilities (states), etc. The departure from Kolmogorov's theory is already implicit in the fact that the quantum random variables do not commute. It is advantageous to set up a noncommutative theory of probability, and one of the requirements is that Kolmogorov's theory is contained as the special case when we restrict to commuting observables. The natural analogue of measure theory for operators is the setting of von Neumann algebras (Kadison and Ringrose 1997).

Classical Probability

The standard approach to probability in the classical world is to associate with each model a Kolmogorov triple $(\Omega, \mathcal{F}, \mathbb{P})$ comprising a measurable space Ω , a sigma-algebra, $\mathcal{F}$, of subsets of Ω , and probability measure $\mathbb{P}$ on the sigma-algebra. Ω covers the entirety of all possible things that may unfold in our model, the elements of $\mathcal{F}$ are distinguished subsets of Ω referred to as events, and $\mathbb{P}[A]$ is the probability of event A occurring. From a practical point of view, we need to frame the model in terms of what we may hope to observe, and these constitute the “events,” $\mathcal{F}$, and from a mathematical point of view, restricting to a sigma-algebra clarifies all the ambiguities while also resolving all the technical issues, pathologies, etc. that would otherwise plague the subject.

A **random variable** is then defined as a function on Ω to a value space, another measurable space $(\Gamma, \mathcal{G})$: so, for each $G \in \mathcal{G}$, the set $X^{-1}[G] = \{\omega \in \Omega : X(\omega) \in G\}$ is an event, i.e., in $\mathcal{F}$. The probability that X takes a value in G is then $\mathbb{K}_X[G] = \mathbb{P}[X^{-1}[G]]$ which produces

the distribution of X as $\mathbb{K}_X = \mathbb{P} \circ \mathbb{X}^{-1}$. Let $X_1, \dots, X_n$ be random variables and then their joint probabilities are also well-defined:

$$\begin{aligned} \mathbb{K}_{X_1, \dots, X_n} [G_1, \dots, G_n] \\ = \mathbb{P} [X_1^{-1} [G_1] \cap \dots \cap X_n^{-1} [G_n]]. \end{aligned} \quad (1)$$

Let $\mathcal{A}$ be a sub-sigma-algebra of $\mathcal{F}$. The collection of bounded $\mathcal{A}$ -measurable (complex-valued) functions will be denoted as $\mathcal{A} = L^\infty(\Omega, \mathcal{A})$. This is an example of a $*$ -algebra of functions. We now show that there is a natural identification between σ -algebras of subsets of Ω and $*$ -algebras of functions on Ω . First we need some definitions.

Definition 1 A sequence $(f_n)_n$ of functions on Ω is said to be a **positive bounded monotone sequence** if there exists a finite constant $c > 0$ such that $0 \leq f_n \leq c$ and $f_n \leq f_{n+1}$ for each n . A $*$ -algebra of functions $\mathcal{A}$ on Ω is said to be a **monotone class** if every positive bounded monotone sequence in $\mathcal{A}$ has its limit in $\mathcal{A}$.

The next result can be found in Protter (2005).

Theorem 1 (Monotone class theorem) *Given a monotone class $*$ -algebra of functions, $\mathcal{A}$, on Ω . Then $\mathcal{A} = L^\infty(\Omega, \mathcal{A})$ where $\mathcal{A}$ is precisely the σ -algebra generated by $\mathcal{A}$ itself.*

Conditional probabilities are naturally defined: the probability that event A occurs given that event B occurs is

$$\mathbb{P}[A|B] \triangleq \frac{\mathbb{P}[A \cap B]}{\mathbb{P}[B]}. \quad (2)$$

This is a simple “renormalization” of the probability: one restricts the outcomes in A which also lie in B , weighted as a proportion out of all B , rather than Ω .

Quantum Probability Models

The standard presentation of quantum mechanics takes physical quantities (observables) to be self-adjoint operators on a fixed Hilbert space $\mathfrak{h}$ of wavefunctions. The normalized elements of $\mathfrak{h}$ are the **pure states**, and the expectation of an observable X for a pure state $\psi \in \mathfrak{h}$ is given

$\mathbb{E}[X] = \langle \psi | X \psi \rangle$. As such, observables play the role of random variables. More generally, we encounter quantum expectations of the form

$$\mathbb{E}[X] = \text{tr} \{ \rho X \} \quad (3)$$

where $\rho \geq 0$ is a trace-class operator normalized so that $\text{tr} \{ \rho \} = 1$. The operator ρ is called a **density matrix** and in the pure case corresponds to $\rho = |\psi\rangle\langle\psi|$.

Definition 2 A **quantum probability space** $(\mathfrak{A}, \mathbb{E})$ consists of a von Neumann algebra $\mathfrak{A}$ and a state $\mathbb{E}$ (assumed to be continuous in the normal topology).

When $\mathfrak{A}$ is commutative, then the quantum probability space is isomorphic to a Kolmogorov model. Let us motivate now why von Neumann algebras are the appropriate object. Positive operators are well defined, and we may say $X \leq Y$ if $Y - X \geq 0$. In particular, the concept of a positive bounded monotone sequence of operators makes sense, as does a monotone class algebra of operators.

Theorem 2 (van Handel 2007) *A collection of bounded operators over a fixed Hilbert space is a von Neumann algebra if and only if it is a monotone class $*$ -algebra.*

Specifically, we see that this recovers the usual monotone class theorem when we further impose commutativity of the algebra. A state on a von Neumann algebra, $\mathfrak{A}$, is then a normalized positive linear map from $\mathfrak{A}$ to the complex numbers, that is, $\mathbb{E}[1] = 1$, $\mathbb{E}[\alpha A + \beta B] = \alpha \mathbb{E}[A] + \beta \mathbb{E}[B]$, $\mathbb{E}[X] \geq 0$, whenever $X \geq 0$. Note that if (X_n) is a positive bounded monotone sequence with limit X , then $\mathbb{E}[X_n]$ converges to $\mathbb{E}[X]$ – this in fact equivalent to the condition of continuity in the normal topology and implies that $\mathbb{E}$ to take the form (3), for some density matrix ρ , (Kadison and Ringrose 1997).

Definition 3 An observable is referred to as a **quantum event** if it is an orthogonal projection. If a quantum event A corresponds to a projection P_A , then its probability of occurring is $\text{Pr} \{A\} = \text{tr} \{ \rho P_A \}$.

The requirement that P_A is an orthogonal projection means that $P_A^2 = P_A = P_A^\dagger$. The complement to the event A , which is *not* A , will be denoted as $\bar{A}$ and is the orthogonal projection given by the orthocomplement $P_{\bar{A}} = \mathbb{1} - P_A$, where $\mathbb{1}$ is the identity operator on $\mathfrak{h}$. A von Neumann algebra is a subalgebra of the bounded operators on $\mathfrak{h}$ with good closure properties: crucially it will be generated by its projections. So the von Neumann algebra generated by a collection of quantum events is the natural analogue of a sigma-algebra of classical events.

However, the new theory of quantum probability will have features not present classically. For instance, the notion of a pair of events, A and B , occurring jointly is not generally meaningful. In fact, $P_A P_B$ is in general not self-adjoint, and so it does not correspond to a quantum event. We therefore cannot interpret $\text{tr}\{\rho P_A P_B\}$ as the joint probability for quantum events A and B to occur.

Proposition 1 *The product $P_A P_B$ is an event (i.e., an orthogonal projection) if and only if P_A and P_B commute.*

Proof. Self-adjointness of $P_A P_B$ is enough to give the commutativity since then $P_A P_B = (P_A P_B)^* = P_B P_A$ as both P_A and P_B are self-adjoint. We then see that $(P_A P_B)^2 = P_A P_B P_A P_B = P_A^2 P_B^2 = P_A P_B$.

As such, given a pair of quantum events A and B , it is usually meaningless to speak of their joint probability $\text{Pr}\{A, B\}$ for a fixed state ρ . An exception is made when the corresponding projectors commute in which case we say the events are compatible and take the probability to be $\text{Pr}\{A, B\} \equiv \text{tr}\{\rho P_A P_B\}$.

By the spectral theorem, every observable may be written as

$$X = \int_{-\infty}^{\infty} x P_X[dx] \quad (4)$$

where $P_X[dx]$ is a projection valued measure, normalized so that $P_X[\mathbb{R}] = \mathbb{1}$, the identity operator. The measure is supported on the spectrum of X which is, of course, real by self-adjointness. In particular, if G_1 and G_2 are non-overlapping

Borel subsets of $\mathbb{R}$, then $P_X[G_1]$ and $P_X[G_2]$ project onto mutually orthogonal projections.

The orthogonal projection $P_X[G]$ then corresponds to the quantum event that X is measured to have a value in the subset G . The smallest von Neumann algebra containing all the projections $P_X[G]$ will be denoted as $\mathfrak{F}_X$ and plays an analogous role to the sigma-algebra generated by a random variable.

Once we fix the density matrix ρ , the spectral decomposition leads to the probability distribution of observable X : $\mathbb{K}_X[dx] = \text{tr}\{\rho P_X[dx]\}$. We say that observables $X_1, \dots, X_n$ are **compatible** if the quantum events they generate are compatible. In this case

$$\text{tr}\left\{\rho e^{i \sum_{k=1}^n u_k X_k}\right\} \equiv \int e^{i \sum_{k=1}^n u_k x_k} \mathbb{K}_{X_1, \dots, X_n}[dx_1, \dots, dx_n], \quad (5)$$

where $\mathbb{K}_{X_1, \dots, X_n}[dx_1, \dots, dx_n]$ defines a probability measure on the Borel sets of $\mathbb{R}^n$. This may be no longer true if we drop the compatibility assumption!

We remark that, given a collection of observables $X_1, \dots, X_n$, we can construct the smallest von Neumann algebra containing all their individual quantum events; this will typically be a non-commutative algebra and will effectively play the role of a sigma-algebra generated by random variables.

Positivity preserving measurable mappings are the natural morphisms between Kolmogorov spaces. The situation in quantum probability is rather more prescriptive.

First note that if $\mathfrak{A}$ and $\mathfrak{B}$ are von Neumann algebras, then so too is their formal tensor product. A map $\Phi : \mathfrak{F} \rightarrow \mathfrak{F}$ between von Neumann algebras is positive if $\Phi(A) \geq 0$ whenever $A \geq 0$. However, we need a stronger condition. The mapping has the extension $\tilde{\Phi}_{\mathfrak{F}} : \mathfrak{A} \otimes \mathfrak{F} \rightarrow \mathfrak{B} \otimes \mathfrak{F}$ for a given von Neumann algebra $\mathfrak{B}$ by $\tilde{\Phi}_{\mathfrak{F}}(A \otimes F) = \Phi(A) \otimes F$. We say that Φ is **completely positive (CP)** if $\tilde{\Phi}_{\mathfrak{F}}$ is positive for any $\mathfrak{F}$.

A **morphism between a pair of quantum probability spaces** (Maassen 1988), $\Phi :$

$(\mathfrak{A}_1, \mathbb{E}_1) \mapsto (\mathfrak{A}_2, \mathbb{E}_2)$ is a completely positive map with the properties $\Phi(\mathbb{1}_{\mathfrak{A}_1}) = \mathbb{1}_{\mathfrak{A}_2}$ and $\mathbb{E}_2 \circ \Phi = \mathbb{E}_1$. Despite its rather trivial-looking appearance, the CP property is actually quite restrictive.

Quantum Conditioning

The conditional probability of event A occurring given that B occurs is defined by $\Pr\{A|B\} = \frac{\Pr\{A, B\}}{\Pr\{B\}}$. In quantum probability, $\Pr\{A, B\}$ may make sense as a joint probability only if A and B are compatible; otherwise there is the restriction that A is measured before B .

Let X be an observable with a discrete spectrum (eigenvalues). If we start in a pure state $|\psi_{\text{in}}\rangle$ and measure X to record a value x , then this quantum event has corresponding projector $P_X(x)$. Von Neumann's projection postulate states that the state after measurement is proportional to

$$|\psi_{\text{out}}\rangle = P_X(x) |\psi_{\text{in}}\rangle \quad (6)$$

and that the probability of this event is $\Pr\{X = x\} = \langle \psi_{\text{in}} | P_X(x) | \psi_{\text{in}} \rangle \equiv \langle \psi_{\text{out}} | \psi_{\text{out}} \rangle$. Note that $|\psi_{\text{out}}\rangle$ is not normalized! A subsequent measurement of another discrete observable Y , leading to eigenvalue y , will result in $|\psi_{\text{out}}\rangle = P_Y(y) P_X(x) |\psi_{\text{in}}\rangle$ and so (ignoring dynamics from the time being)

$$\begin{aligned} \Pr\{X = x; Y = y\} &= \langle \psi_{\text{out}} | \psi_{\text{out}} \rangle \\ &= \langle \psi_{\text{in}} | P_Y(y) P_X(x) P_Y(y) | \psi_{\text{in}} \rangle. \end{aligned} \quad (7)$$

This needs to be interpreted as a sequential probability – event $X = x$ occurs first, and $Y = y$ second – rather than a joint probability. If X and Y do not commute, then the order in which they are measured matters as $\Pr\{X = y; Y = y\}$ may differ from $\Pr\{Y = y; X = x\}$.

Lemma 1 *Let P and Q be orthogonal projections, then the properties $QPQ = PQP$ and $PQP = QP$ are equivalent to $[Q, P] = 0$.*

Proof. We begin by noting that $[P, Q]^* [P, Q] = QPQ - PQPQ + PQP - QPQP$. This may

be rewritten as $(Q - P)(QPQ - PQP)$, so if $QPQ = PQP$, then $[P, Q] = 0$. If we have $PQP = QP$, then $[P, Q]^* [P, Q] \equiv QPQ - QPQ + PQP - QP = PQP - QP = 0$ and so $[P, Q] = 0$. Conversely, if P and Q commute then $QPQ = PQP$ and $PQP = QP$ hold true.

Corollary 1 *If we have $\Pr\{X = x; Y = y\}$ equal to $\Pr\{Y = y; X = x\}$ for all states $|\psi_{\text{in}}\rangle$ and all eigenvalues x and y are equal, then X and Y are compatible.*

The symmetry implies that $P_Y(y) P_X(x) P_Y(y)$ equals $P_X(x) P_Y(y) P_X(x)$, and so the spectral projections of X and Y commute.

Corollary 2 *If for all states $|\psi_{\text{in}}\rangle$ whenever we measure X and then Y and then X again, we always record the same value for X , and then X and Y are compatible.*

Setting $|\psi_{\text{out}}\rangle = P_Y(y) P_X(x) |\psi_{\text{in}}\rangle$, we must have that $P_X(x) |\psi_{\text{out}}\rangle = |\psi_{\text{out}}\rangle$; if this is true for all $|\psi_{\text{in}}\rangle$, then $P_X(x) P_Y(y) = P_X(x) P_Y(y) P_X(x)$ which likewise implies that $[P_X(x), P_Y(y)] = 0$.

Conditioning over Time

The dynamics under a (possibly time-dependent) Hamiltonian $H(t)$ is described by the two-parameter family of unitary operators

$$U(t, s) = \mathbb{1} - i \int_s^t H(\tau) U(\tau, s) d\tau, \quad t \geq s. \quad (8)$$

This is the solution to $\frac{\partial}{\partial t} U(t, s) = -i H(t) U(t, s)$, $U(s^-, s) = \mathbb{1}$. We have the **flow identity**

$$U(t_3, t_2) U(t_2, t_1) = U(t_3, t_1) \quad (9)$$

whenever $t_3 \geq t_2 \geq t_1$. In the special case where H is constant, we have $U(t, s) = e^{-i(t-s)H}$. It is convenient to introduce the maps ($t_2 > t_1$)

$$J_{(t_1, t_2)}(X) = U(t_2, t_1)^* X U(t_2, t_1) \quad (10)$$

and, from the flow identity (9), $J_{(t_1, t_2)} \circ J_{(t_2, t_3)} = J_{(t_1, t_3)}$ whenever $t_3 > t_2 > t_1$.

We now consider an experiment where we measure observables $Z_1, \dots, Z_n$ at times $t_1 < t_2 < \dots < t_n$ during a time interval 0 to T . At the end of the experiment, if we measure $Z_1 \in G_1, \dots, Z_n \in G_n$, then the output state should be

$$|\psi_{\text{out}}\rangle = U(T, t_n) P_{Z_n}[G_n] U(t_n, t_{n-1}) \dots U(t_2, t_1) P_{Z_1}[G_1] U(t_1, 0) |\psi_{\text{in}}\rangle. \quad (11)$$

It is convenient to introduce the observables

$$Y_k = J_{(0, t_k)}(Z_k). \quad (12)$$

The quantum event $Y_k \in G_k$ at time t_k is then $P_{Y_k}[G_k] = J_{(0, t_k)}(P_{Z_k}[G_k])$. The flow identity implies $U(t_k, t_{k-1}) = U(t_k, 0) U(t_{k-1}, 0)^*$, and we find

$$\begin{aligned} |\psi_{\text{out}}\rangle &= U(T, 0) J_{(0, t_n)} \\ &\quad (P_{Z_n}[G_n]) \dots J_{(0, t_1)}(P_{Z_1}[G_1]) |\psi_{\text{in}}\rangle \\ &= U(T, 0) P_{Y_n}[G_n] \dots P_{Y_1}[G_1] |\psi_{\text{in}}\rangle. \end{aligned} \quad (13)$$

We therefore have the probability

$$\begin{aligned} \Pr\{Y_1 \in G_1; \dots; Y_n \in G_n\} &= \langle \psi_{\text{out}} | \psi_{\text{out}} \rangle \\ &= \text{tr} \{ P_{Y_n}[G_n] \dots P_{Y_1}[G_1] \rho \\ &\quad P_{Y_1}[G_1] \dots P_{Y_n}[G_n] \}, \end{aligned}$$

where ρ is the initial state. Note that this takes the **pyramidal** form.

Here the Z_k are all to be understood as observables specified in the Schrödinger picture at time 0 – what we measure are the Y_k which are the Z_k at respective times t_k . The answer depends on the chronological order $t_1 < t_2 < \dots < t_n$.

It is tempting to think of $\{Y_k : k = 1, \dots, n\}$ as a discrete time stochastic process, but some caution is necessary. We cannot generally permute the events $Y_1 \in G_1; \dots; Y_n \in G_n$, so we do not have the symmetry usually associated with Kolmogorov's reconstruction theorem.

Proposition 2 *The finite-dimensional distributions satisfy the marginal consistency for the most recent variable. Specifically, this means that*

$$\begin{aligned} \sum_G \Pr\{Y_1 \in G_1; \dots; Y_n \in G\} \\ = \Pr\{Y_1 \in G_1; \dots; Y_{n-1} \in G_{n-1}\} \end{aligned} \quad (14)$$

where the sum is over a collectively exhaustive mutually exclusive set $\{G\}$.

Proof. We have

$$\sum_G \Pr\{Y_1 \in G_1; \dots; Y_n \in G\} \quad (15)$$

$$\begin{aligned} &= \sum_G \text{tr} \{ P_{Y_{n-1}}[G_{n-1}] \dots P_{Y_1}[G_1] \rho \\ &\quad P_{Y_1}[G_1] \dots P_{Y_{n-1}}[G_{n-1}] P_{Y_n}[G] \} \end{aligned} \quad (16)$$

but $\sum_G P_{Y_n}[G] \equiv \mathbb{1}$, so we obtain the desired reduction.

As an example, suppose that $\{A_k\}$ is a collection of quantum events occurring at a fixed time t_1 which are mutually exclusive (i.e., their projections project onto orthogonal subspaces). Their union $\cup_k A_k$ makes sense and corresponds to the projection onto the direct sum of these subspaces. Now if B is an event at a later time t_2 , then typically $\sum_k \Pr\{A_k; B\}$ is not the same as $\Pr\{\cup_k A_k; B\}$. The well-known two-slit experiment fits into this description, with A_k the event that an electron goes through slit k ($k = 1, 2$) and B the subsequent event that it hits a detector.

Marginal consistency is a property we take for granted in classical stochastic processes and is an essential requirement for Kolmogorov's reconstruction theorem. However, in the quantum setting, it is only guaranteed to work for the last measured observable. For instance, it may not

apply to Y_{n-1} unless we can commute its projections with $P_{Y_n}[G_n]$. The most recent measured observable has the potential to **demolish** all the measurements beforehand.

Bell's Inequalities

A Bell inequality is any constraint that applies to classical probabilities but which may fail in quantum probability. We look at one example due to Eugene Wigner.

Proposition 3 (A Bell Inequality) *Given three (classical) events A, B, C then we always have*

$$\Pr\{A, C\} \leq \Pr\{A, \overline{B}\} + \Pr\{B, C\}. \quad (17)$$

Proof. From the marginal property, we have the following three classical identities $\Pr\{A, \overline{B}\} = \Pr\{A, \overline{B}, C\} + \Pr\{A, \overline{B}, \overline{C}\}$, $\Pr\{B, C\} = \Pr\{A, B, C\} + \Pr\{\overline{A}, B, C\}$, and $\Pr\{A, C\} = \Pr\{A, B, C\} + \Pr\{A, \overline{B}, C\}$. We therefore have that

$$\begin{aligned} & \Pr\{A, \overline{B}\} + \Pr\{B, C\} - \Pr\{A, C\} \\ &= \Pr\{A, \overline{B}, \overline{C}\} + \Pr\{\overline{A}, B, C\} \geq 0. \end{aligned} \quad (18)$$

The proof relies on the fact that marginal consistency is always valid for classical events. Suppose that the A, B, C are quantum events, say Y_k taking a value in G_k at time t_k ($k = 1, 2, 3$), and chronologically ordered ($t_1 < t_2 < t_3$). Then only the first of the three classical identities is guaranteed in quantum theory (marginal consistency for the latest event at time t_3 only). The remaining two may fail, and it is easy to construct a quantum system where inequality (17) is violated.

Quantum Filtering

Given the issues raised above, one may ask whether it is actually possible to track a quantum system over time?

We shall say that the process $\{Y_k: k=1, \dots, n\}$ is **essentially classical** whenever all the observables are compatible. In this case its

finite-dimensional distributions satisfy all the requirements of Kolmogorov's theorem, and so we can model it as a classical stochastic process. The von Neumann algebra $\mathfrak{V}_n$ they generate will be commutative, and we have $\mathfrak{V}_n \subset \mathfrak{V}_{n+1}$ (a filtration of von Neumann algebras!).

For the tracking over time to be meaningful, we ask for the observed process to be essentially classical – this is the **self-non-demolition property** of the observations.

Let $X_n = J_{(0, t_n)}(X)$ be an observable X at time t_n . Suppose that it is compatible with $\mathfrak{V}_n$, then we are lead to a well-defined classical joint distribution $\mathbb{K}_{X_n, Y_1, \dots, Y_n}$ from which we may compute the conditional probability $\mathbb{K}_{X_n|Y_1, \dots, Y_n}$. This means that $\pi_{t_n}(X) = \mathfrak{E}[X_n|\mathfrak{V}_n]$ is well-defined.

We only try to condition those observables that are compatible with the measured observables! This is known as the **non-demolition property**.

Conditioning in Quantum Theory

The natural analogue of conditional expectation in quantum theory would be a projective morphism (CP map) from a von Neumann algebra into a sub-von Neumann algebra. However, this does not to always exist in the noncommutative case. Given our discussions above, this is not surprising.

In general, be $\mathfrak{V}$ be a sub-von Neumann algebra of a von Neumann algebra $\mathfrak{B}$, then its commutant is the set of all operators in $\mathfrak{B}$ which commute with each element of $\mathfrak{V}$, that is

$$\mathfrak{V}' = \{X \in \mathfrak{B} : [X, Y] = 0, \forall Y \in \mathfrak{V}\}.$$

Why explain. The von Neumann algebra generated by $\mathfrak{V}$ and fixed element $X \in \mathfrak{V}'$ will again be a commutative, so the conditional expectation of X onto $\mathfrak{V}$ is well defined. Physically, it means that $X \in \mathfrak{V}'$ is compatible with $\mathfrak{V}$, so standard classical probabilistic constructs are valid.

As an illustration, suppose that the von Neumann algebra of a system of interest is $\mathfrak{A}$ and its environment's is $\mathfrak{E}$. Let X be a simple observable of the system, say with spectral decomposition $X = \sum_x x R_x$ where $\{R_x\}$ is a set of mutually orthogonal projections. Similarly, let

$Z = \sum_y y Q_y$ be an environment observable. We entangle the system and environment with a unitary U (acting on $\mathfrak{A} \otimes \mathfrak{E}$) and measure the observable $Y = U^*(\mathbb{1}_{\mathfrak{A}} \otimes Z)U \equiv \sum_y P_y$. Here, the event corresponding to measuring eigenvalue y of Y is $P_y = U^*(\mathbb{1}_{\mathfrak{A}} \otimes Q_y)U$. The observables $X_1 = U^*(X \otimes \mathbb{1}_{\mathfrak{E}})U$ and Y commute, and so they have a well-defined joint probability to have eigenvalues x and y , respectively, for a fixed state $\mathbb{E}$: $p(x, y) = \mathbb{E}[U^*(R_x \otimes Q_y)U]$. We may think of X_1 as X evolved by one time step. Its conditional expectation given the measurement of Y is then $\mathbb{E}[X_1|\mathfrak{Y}] = \sum_{x,y} x p(x|y) P_y$ where $p(x|y) = p(x, y)/p(y)$, with $p(y) = \sum_x p(x, y)$.

Summary and Future Directions

Quantum theory can be described in a systematic manner, despite the frequently sensationalist presentations on the subject. Getting the correct mathematical setting allows one to develop an operational approach to quantum measurements and probabilities. We described the quantum probabilistic framework which uses von Neumann algebras in place of measurable functions and shown how some of the usual concepts from Kolmogorov's theory carry over. However, we were also able to highlight which features of the classical world may fail to be valid in quantum theory.

What is of interest to control theorists is that the extraction of information from quantum measurements can be addressed and, under appropriate conditions, filtering can be formulated. As we have seen, measuring quantum systems over time is problematic. However, the self-non-demolition property of the observations and the non-demolition principle are conditions which guarantee that the filtering problem is well-posed. These conditions are met in continuous-time quantum Markovian models (by causality, prediction turns out to be well-defined, though not necessarily smoothing!). Explicit forms for the filter were given by Belavkin (1980); see also Bouten et al. (2007).

Connected and Automated Vehicles

A. A. Kurzhanskiy, F. Borrelli, and P. Varaiya
University of California, Berkeley, Berkeley,
CA, USA

Abstract

This is a selective survey of technologies for the coordinated control of vehicles. The vehicles are connected: they may communicate with each other and with the infrastructure. Moreover, some vehicle planning and actuation functions are coordinated and automated, i.e., determined by on-board or (cloud-based) infrastructure processors. The entry emphasizes technologies that use communication to coordinate the movement of vehicles and deemphasizes developments that focus on autonomous driving. Hence, sensing, planning, and control technologies that are oriented to autonomous (driver-less) vehicles are not considered. The entry evaluates coordinated control technologies in terms of their contribution to greater safety, mobility, and efficiency of the US road transportation system. Safety benefits translate to reduced crash rates; mobility improvements lead to increased throughput of the road system; and higher efficiency means reduced energy consumption for a given pattern of traffic.

Keywords

Connected automated vehicles (CAVs) · V2X · Platoons · Cruise control · ACC · CACC · PCC · MPC · Power train · SPaT

Introduction

Connected and automated vehicles (CAVs) have the potential to disrupt mobility, extending what is possible with driving automation and connectivity alone. Applications include real-time control and planning with increased awareness,

routing with micro-scale traffic information, coordinated platooning using traffic signals information, and eco-mobility on demand with guaranteed parking. This entry introduces the technology, the control problems, and opportunities of CAVs and surveys the state of the art of CAVs.

We start by reviewing the definition of automated driving. In 2014, the Society of Automotive Engineers (SAE International) released a six-level classification of automated driving, known as SAE J3016 (Taxonomy and Definitions for Terms Related to On-Road Motor Vehicle Automated Driving Systems [2014](#)):

- **Level 0.** The automated system has no vehicle control, but may issue warnings.
- **Level 1.** An ADAS on the vehicle can assist the human driver with steering and braking/accelerating. Here, the automated system may include adaptive cruise control (ACC) or cooperative ACC (CACC), parking assistance with automated steering, and lane keeping assistance.
- **Level 2.** An ADAS on the vehicle can control both steering and braking/accelerating under some circumstances. The driver must continue to pay full attention (“monitor the driving environment”) at all times and perform the rest of the driving task. The automated system must deactivate immediately upon takeover by the driver.
- **Level 3.** An automated driving system (ADS) on the vehicle can perform all aspects of the driving task within certain operational environments (e.g., freeways). Within these environments, the driver can safely turn their attention away from driving task. However, the driver must be ready to take back control at any time the ADS requests the driver to do so. In all other circumstances, the driver performs the driving task.
- **Level 4.** An ADS on the vehicle can itself perform all driving tasks and monitor the driving environment – essentially, do all the driving – in certain circumstances. The driver should enable the ADS only when it is safe to do

so, but when the ADS is enabled, driver's attention is no longer required.

- **Level 5.** An ADS on the vehicle can do all the driving in all circumstances, where it is legal to drive. The human occupants are just passengers and need not be involved in driving, other than starting the system and setting the destination.

The most advanced automated production vehicles today belong to Level 2: functional motion control systems exist; however, sensing and perception technologies are not yet able to fully replace the driver even in limited operational environments.

Connected vehicles are vehicles that use any of a number of different communication technologies to communicate with the road actors (such as other vehicles, pedestrian, bicyclist) and infrastructure (such as traffic lights and parking facilities). Some common definitions include:

- *Vehicle-to-vehicle (V2V)* enables vehicles to wirelessly exchange information about their speed, location, and heading. The technology behind V2V communication allows vehicles to broadcast and receive omni-directional messages (up to ten times per second), creating a 360-degree “awareness” of other vehicles in proximity.
- *Vehicle-to-infrastructure (V2I)* captures vehicle-generated traffic data, wirelessly providing information such as advisories from the infrastructure to the vehicle that inform the driver of safety, mobility, and/or environment-related conditions (e.g., signals).
- *Vehicle-to-pedestrian (V2P)* encompasses a broad set of road users including people walking, children being pushed in strollers, people using wheelchairs or other mobility devices, passengers embarking and disembarking buses and trains, and cyclists.
- *Vehicle-to-cloud (V2C)* enables communication with the “cloud.” This makes a vehicle an Internet-connected endpoint equipped with a data storage and analytics capabilities of the cloud.

All of these communication technologies are addressed as *vehicle-to-everything (V2X)*. Part of V2X messaging is defined by SAE in its J2735 standard (Dedicated Short Range Communications [DSRC](#)). V2X refers to an intelligent transport system where all vehicles and infrastructure systems are interconnected with each other.

Vehicle connectivity enables many convenience features and services, including emergency calls, toll payment, and infotainment. It has also emerged as a technology to improve safety and performance and enable vehicle cooperation.

CAV technology has the potential to extend what is possible with driving automation and vehicle connectivity separately. It is envisioned that V2X will provide precise knowledge of the traffic situation across the entire road network, which in turn, using automation, should help in:

1. Reducing accidents – This provides crash-free driving and improved vehicle safety; a vehicle can monitor the environment continuously, making up for lapses in driver attention.
2. Optimizing traffic flows – This will reduce the need for building new infrastructure and reduce maintenance costs. This will also reduce uncertainty in travel times via real-time, predictive assessment of travel times on all routes.
3. Improving energy efficiency through more efficient driving; lighter, more fuel-efficient vehicles; and efficient infrastructure.

CAV Ecosystem

CAV applications for optimization of safety, traffic flow, and energy consumption build upon the extensive information fed to automatic control algorithms. The information exchange and control happens on three levels: vehicle level, roadside level, and network level. Figure 1 shows the information flow diagram articulating the three levels of control. Data generated by CAVs,

Connected and Automated Vehicles, Fig. 1 Information flow in CAV applications

roadside detection, and control units form the foundation of this diagram.

A CAV can provide information about its location coming from an onboard GNSS (Global Navigation Satellite System is the general term for GPS, GLONASS, Galileo, BeiDou, and other regional navigation systems.); dynamics (heading, speed, acceleration); and, possibly, intent to turn or switch lanes (when a blinker is on) with some periodicity (typically, 10 Hz). Present communication technologies that a CAV can use to send these data are dedicated short-range communication (DSRC) and cellular networks (LTE and 5G).

DSRC is a wireless communication technology, mostly conceived for active safety and convenience services. Advantages of the DSRC technology include security, low latency, interoperability, and resilience to extreme weather conditions. The DSRC technology may also be used to improve GPS accuracy (Alam et al. 2011) and for geo-fencing. One problem of DSRC

is that it requires special hardware. Another limitation is its short-range limitation enabling CAV communication only with nearby CAVs and infrastructure. DSRC is not suitable for transferring large data.

5G offers both, the communication with other vehicles and infrastructure and the access to multimedia and cloud services. Using 5G, a CAV would be able to provide information coming from its onboard sensors that can include lidar, radar, cameras, and ultrasonic sensors. This information would describe the CAV environment – presence and density of other agents (other vehicles, cyclists, pedestrians); workzones; obstacles; and hazards.

V2X messages presently defined in the SAE J2735 standard (Dedicated Short Range Communications [DSRC](#)) are mostly oriented toward awareness and safety applications. Advanced vehicle cooperation, including multi-vehicle formations and cooperative awareness, requires more complex protocols (van de Sluis

et al. 2015), for which standards (such as the announced J2945/6 standard) are still under development. An appealing niche for cooperative vehicles is freight transportation; heavy-duty vehicles capable of automated driving and V2V communication can form *platoons* and drive at small inter-vehicular distance, thereby reducing their air drag resistance and fuel consumption (Peloton Technology).

The roadside infrastructure includes complex systems for traffic monitoring and control deployed on freeways and at urban intersections. Freeways are instrumented with systems for vehicle detection, to monitor and potentially control the traffic flow. A variety of detection technologies are employed, including in-roadway sensors (loop detectors, magnetic detectors, magnetometers) and over-roadway sensors (cameras, radars, ultrasonic, infrared, and acoustic sensors) (Gibson et al. 2007). The use of sensors in freeways includes data collection (vehicle occupancy, speed, type) for monitoring and planning of road use (California Department of Transportation) and active traffic control via ramp metering.

A typical instrumented intersection (see, e.g., Lioris et al. 2017) features in-pavement sensors, such as loop detectors or magnetic sensors, that detect the presence of vehicles at a stop bar. Additional sensors, those located on the approaches to the intersection and those in departure lanes exiting the intersection, can also be used to estimate the speed and turn movements of vehicles (Coogan et al. 2016). The signal phase and timing (referred to as *SPaT* and describing the current combination of signal phases and the remaining time until the next change of phase) can be retrieved directly from the controller, or indirectly via image analysis. Controllers can implement a fixed cycle, change green times depending on immediate traffic conditions, or implement more advanced control strategies adapting to the congestion level; pedestrians can be part of the cycle or make requests with buttons. Intersections can be instrumented to broadcast messages to nearby vehicles using DSRC. The SAE standard J2735 (Dedicated Short Range Communications

DSRC) includes messages for signal phase and timing and intersection geometry. Note that the timing part is deterministic only if the controller has a fixed cycle; otherwise, the timing is inherently uncertain, because of the stochastic nature of traffic.

CAV communication with unconnected vehicles, cyclists, and pedestrians happens via the connected roadside infrastructure, provided that it has necessary detection capabilities. When unconnected agents are detected, the roadside infrastructure broadcasts information about their presence in a given lane or at a crosswalk. Similarly, the warnings about approaching trains are broadcasted at rail crossings.

Beyond intersections and traffic signals, urban infrastructure includes fuel stations, charging stations, and parking infrastructure. A connected charging and parking infrastructure enables better routing of vehicles and more effective pricing schemes. Moreover since vehicle charging has a significant effect on grid balancing and smart grids (Clement-Nyns et al. 2010, 2011; Fan 2012), connectivity is expected to play a major role in grid-vehicle interaction.

Modern road and traffic map services provide information that goes beyond the maps for navigation, including *static* information, such as road grade, road curvature, location of intersections, lane maps, speed limits, location of fuel and charging stations, and intersection average delays, and *dynamic* information, such as traffic speed, availability and price of fuel and charging stations, intersection delays, traffic congestion, road works, and weather conditions. Historical data pinned to maps can be relevant for planning problems, such as vehicle routing and reference velocity generation. Examples include traffic congestion on freeways (California Department of Transportation) and signal phase and timing data (Ibrahim et al. 2017); in both cases, historical data give deeper insight on traffic patterns. CAVs can use cloud services to do heavy-duty computations remotely, thus relaxing the on-board computational requirements. Computations moved to the cloud may include (dynamic) routing and long-term trajectory optimization.

Connected and Automated Vehicles, Table 1 Categorization of CAV applications

	Safety	Traffic efficiency	Energy efficiency
Vehicle level	Balancing safety and performance in car following	CACC for throughput increase on freeways and at arterial intersections	Powertrain energy minimization
Roadside level	Intelligent intersection that ensures safe crossing for all travel modes	Platoon coordination at critical junctions to maximize road capacity utilization	SPaT prediction and speed advisory for minimizing energy consumption
Network level	Improving situational awareness at hazardous locations	Routing to minimize travel time and congestion	Routing to minimize energy consumption

Examples of CAV applications categorized by the level of information and control and by the area of impact are summarized in Table 1.

Control Systems for CAV

This section discusses relevant applications of control systems for CAV operation. We will briefly cover vehicle motion control, decision-making and motion planning, coordination of CAVs at junctions, and platoon coordination. We will not address route optimization problems here, as they are often solved in the cloud and have a wider application than just CAVs.

Motion Control

Motion control ensures that the vehicle's longitudinal and lateral motion follows a reference trajectory or path. The existing longitudinal control approaches are distinguished by their use of external information: predictive cruise control (PCC), ACC, CACC, and connected cruise control (CCC).

PCC tracks a reference velocity that is generated using preview information. The information can be *static* (e.g., road grade and speed limits) or *dynamic* but slowly changing (e.g., traffic speed).

ACC detects any preceding vehicle and adjusts speed to avoid collisions. ACC is designed to enhance passengers' safety and comfort and to improve road throughput and energy efficiency.

CACC is an enhancement of ACC enabled by communication. The performance of ACC is limited by perception systems that can only measure the relative distance and velocity. V2V communication enables the exchange of vehicle

acceleration (and potentially of its forecast), which is important in dynamic driving scenarios. CACC exploits this additional piece of information to guarantee higher safety and smaller inter-vehicular distance. In addition to improved safety, this can translate into lower energy consumption, higher road throughput, and passenger comfort. For control analysis and synthesis, the multi-vehicle formation can be regarded as a one-dimensional networked dynamic system. Much research has been devoted to multi-agent consensus schemes, regarding CACC as a distributed control problem – see Li et al. (2017) for a detailed survey on CACC. Analysis, design, and synthesis can be addressed by classifying the CAV platoon problem based on:

- *Dynamics*, i.e., the dynamics of each CAV.
- *Information flow network*, i.e., the topology and quality of information flow and the type of information exchanged. Figure 2 depicts some typical communication topologies used in platooning. The information exchanged may just be the current velocity and acceleration or include forecasts thereof and information on lateral motion.
- *Local controller design* and its use of on-board information.
- *Formation geometry*, i.e., vehicle ordering, cruising speed, and inter-vehicle distance.

Note that the dynamics and the distributed controller pertain to the individual CAV, while the information flow network and the formation geometry are properties of the platoon. The latter two can be decided a priori in a specific demonstration but require some form of stan-

Connected and Automated Vehicles, Fig. 2 Information flow topologies in a four-vehicle platoon. The red node indicates the platoon leader. The nomenclature is borrowed from Li et al. (2017) (a) Predecessor Following.

(b) Bidirectional. (c) Predecessor Following Leader. (d) Bidirectional Leader. (e) Two Predecessor Following. (f) Two Predecessor Following Leader

dardization for operation on public roads. CACC can be viewed as a tracking control problem with forecast; as such it has been addressed with a variety of control techniques (Li et al. 2017). Linear consensus control and distributed robust control techniques enable insightful theoretical analysis and can provide guarantees of string stability (Naus et al. 2010).

CCC is essentially an extension of CACC that includes non-CAVs in the formation and relaxes the constraints on the information flow network. A significant difference with CACC is that CCC is not cooperative: the ego-CAV exploits the available V2X information to its advantage, not necessarily to the advantage of all the connected vehicles. We refer the interested reader to Orosz (2016), Zhang and Orosz (2016), and Ge and Orosz (2014) for a detailed theoretical analysis of CCC and to Orosz et al. (2017) for some experimental results.

Lateral control supervises the vehicle motion in the lateral direction, actuating the steering angle or torque. Generally, lateral controllers track a reference trajectory or path ensuring robustness in an uncertain and fast changing environment. Lateral control is tightly connected with the lateral stability of the vehicle, particularly in the presence of static and dynamic obstacles and during operation at the limits of friction (e.g., Funke et al. 2017). In addition to steering, lateral control can exploit differential braking and traction to influence the lateral motion of the vehicle (e.g., Park and Gerdes 2015). In vehicles

with a low degree of automation, lateral control can also just provide assistance to a human driver, implementing a shared control paradigm (Erlien et al. 2015; Ercan et al. 2018).

Decision-Making and Motion Planning

The decision-making control system controls the vehicle behavior (stay in the current lane or change, come to a stop at an intersection, yield to pedestrians, etc.) and on how to translate that behavior into a CAV trajectory. Decision-making for vehicle behavior can be implemented by heuristic rules. Since the intentions of other agents (aside from other CAVs) are uncertain, estimation, prediction, and learning techniques play a major role in this field (Paden et al. 2016).

The high-level specifications from the remote planning and the behavioral decision must then be translated into a path or trajectory for the CAV, taking into account the most recent state and predictions of the surrounding objects. In the literature, *path planning* generally indicates the problem of planning the future motion in the configuration space of the vehicle, while *trajectory planning* indicates the search of a time-parametrized solution (Paden et al. 2016; Katrakazas et al. 2015). Both problems are often formulated as an optimization problem, i.e., in terms of the minimization of some cost functional subject to constraints. Holonomic constraints include collision avoidance constraints and terminal constraints that define safe regions or *driving corridors* from the current to the target

configuration. In path planning, differential constraints are included to enforce some level of smoothness in the solution, for instance, on the path curvature. In trajectory planning, dynamic constraints can be included, and collision avoidance can in principle be enforced not only for static but also for dynamic obstacles.

Optimal path and trajectory planning are both PSPACE-hard in their general formulations. As such, past and current research have focused on computationally tractable approximations, or on methods that apply to specific scenarios. Computational methods for path planning include variational and optimization methods, graph search methods, and incremental search methods. See, respectively, Gerdts et al. (2009), Lima et al. (2017), Zhang et al. (2017), Plessen et al. (2017), Funke and Gerdes (2015), Cirillo (2017), and Kuwata et al. (2009) for some recent examples and Paden et al. (2016) for a detailed review. Trajectory planning can be solved using variational methods in the time domain, or converting it to a path planning problem with a time dimension (Paden et al. 2016).

In CAVs, communication can greatly improve the awareness of other agents and, in general, of the surrounding environment. In fact, CAVs can share not only their own states and predicted motion but also the obstacles that they detect; a distributed perception system can include multiple CAVs, roadside units, and potentially cyclists and pedestrians and can significantly outperform an advanced perception system that only uses on-board sensors. This potential is discussed in Katrakazas et al. (2015). Examples of motion planning applications using forecasts from communication can be found in Plessen et al. (2016, 2018) and Shen et al. (2015). V2V-based coordination (in both one-directional and bi-directional traffic flow) is addressed using optimization methods in Plessen et al. (2016, 2018) and using graph search methods in Shen et al. (2015).

Coordination of CAVs at Junctions

One of the simplest coordination between CAV and traffic lights is minimization of braking and stopping at red lights. A heuristic algorithm was

proposed in, e.g., Koukoumidis et al. (2012). Several optimization-based algorithms have also been proposed in the literature. The optimization goal may be to minimize travel time, reduce acceleration peaks, avoid idling at red lights, or directly minimize energy consumption. Computational approaches include dynamic programming, Dijkstra's shortest path algorithm, MPC, and genetic algorithms.

In an MPC formulation of energy consumption minimization when traveling on a street with signalized intersections, the problem is cast in the longitudinal position domain, as a finite-horizon optimal control problem of the following form (Sun et al. 2020):

$$\begin{aligned} & \underset{u_0, u_1, \dots, u_{N-1}}{\text{minimize}} \quad \sum_{k=0}^{N-1} h(x_k, u_k) \\ & \text{subject to} \quad \left. \begin{aligned} x_{k+1} &= f(x_k, u_k), \\ u_k &\in \mathcal{U}, \quad x_k \in \mathcal{X}, \end{aligned} \right\} k=0, 1, \dots, N-1, \\ & \quad x_0 = x_s, \quad x_N \in \mathcal{X}_N. \end{aligned}$$

We set the state vector as $x = [t, v]^T$ and the input vector as $u = [F_w, F_b]^T$, where t is the travel time, v is the vehicle speed, F_w is the wheel force, and F_b is the braking torque. The longitudinal dynamics is modeled as in Guzzella and Sciarretta (2013), projected into the position domain by the transformation

$$\frac{dv}{dt} = v \frac{dv}{ds},$$

and applies Euler discretization with step S_s , obtaining

$$f(x, u) = \begin{bmatrix} t + \frac{S_s}{v} \\ v + \frac{S_s}{Mv} (F_w - F_b - F_f) \end{bmatrix},$$

where M is the vehicle mass and

$$\begin{aligned} F_f &= Mg \sin \vartheta - Mg(C_r + C_v v) \cos \vartheta \\ &\quad - \frac{1}{2} \rho A C_x v^2, \end{aligned}$$

Connected and Automated Vehicles, Fig. 3 Eco-driving through signalized intersections. (Source: Sun et al. 2020)

g is the gravity constant, ϑ is the (position-dependent) road grade, C_r is the rolling coefficient, C_v is the viscous friction coefficient, ρ is the air density, A is the front area, and C_x is the air drag coefficient. Assuming a fuel-powered vehicle, the cost function is set to the fuel rate $h(x, u) = \dot{m}_f(v, F_w)/v$.

The convex input constraint set $\mathcal{U}$ defines the actuator limits, while the state constraint set describes the surrounding environment. A convex set $\mathcal{X}_1$ models bounds on the speed and the acceleration. The formulation above can accommodate N_s signalized intersections, assuming they can be approximated as points along the route. We assume that every traffic signal has an independent cycle time $c^i \in [0, \bar{c}^i]$, $i = 1, \dots, N_s$, where $c^i = 0$ denotes the beginning of the red light phase and $\bar{c}^i \in \mathbb{R}^+$ is the cycle period. We denote the red light phase duration by $c_r^i \in (0, \bar{c}^i)$ and by t_p^i the time at which the CAV passes through intersection i . In the domain of the intersection cycle time c_i , the passing time is computed as $c_p^i = (c_0^i + t_p^i) \bmod \bar{c}^i$, where c_0^i is the cycle time at $s = 0$. We enforce that intersections are not crossed during red light phases

by $\mathcal{X}_2 = \{t : c_p^i(t) \geq c_r^i, \forall i = 1, \dots, N_s\}$. To summarize, the state constraint set is given by $\mathcal{X} = \mathcal{X}_1 \cap \mathcal{X}_2$. The forecasts of the red phase durations c_r^i is obtained from the SPaT information broadcasted by the connected intersections.

In case some or all of these forecasts are unavailable, one could replace $\mathcal{X}_2$ with a chance constraint

$$\mathcal{X}_3 = \left\{t : \Pr \left[c_p^i(t) \geq c_r^i + \alpha^i \right] \geq 1 - \eta^i, \forall i = 1, \dots, N_s \right\},$$

where $\Pr[A]$ is the probability of event A , $\alpha^i \in [0, \bar{c}^i - c_r^i]$ models the adaptation of the red light phase, and $\eta^i \in [0, 1]$ is the level of constraint enforcement.

Figure 3 shows the solutions to the deterministic problem (i.e., enforcing $\mathcal{X} = \mathcal{X}_1 \cap \mathcal{X}_2$) and to some instances of the robust problem (i.e., enforcing $\mathcal{X} = \mathcal{X}_1 \cap \mathcal{X}_3$ for different values of η^i). There are three intersections here ($N_s=3$) denoted by the red lines that represent red light periods. For each intersection, the blue

line depicts a probability distribution of α_i in the green time period. It can be noted that the deterministic solution crosses the third intersection very close to a phase switching (red to green); conversely, the robust solutions show different levels of conservatism, which can be adjusted by tuning η^i . We refer the reader to Sun et al. (2020) for an extensive analysis, implementation details, and approaches to define X_3 based on historical signal timing data.

Platoon Coordination

Longitudinal control of platoons is mostly regarded as a distributed control problem, but some basic centralized coordination is still required; in particular, the formation geometry (inter-vehicular spacing policy, cruising speed, vehicle ordering) and the information flow network (communication topology and quality, communication protocol) affect platoon safety and performance. These aspects have not been standardized to date, and due to the heterogeneity of vehicles, sensors, actuators, and communication technologies available on the market, they could reasonably be coordinated remotely on a case-by-case basis. For instance, some communication topologies listed in Fig. 2 may not be feasible, depending on the number and the specific instrumentation of the vehicles involved in the platoon. Another example is the choice of the inter-vehicle spacing policy, which depends on a number of factors, including the dynamics and imperfections of sensors, actuators, and wireless communication.

For a formed platoon, motion is mostly longitudinal within a lane, although lateral motion is needed for lane changes and collision avoidance. Platoon management (formation and dissolution) is a closely related problem which also requires coordination. A CAV that joins or leaves a platoon needs authority on both longitudinal and lateral motion, while the vehicles in the platoon may only move longitudinally to open or close a gap. Merging of (or splitting into) two platoons is not fundamentally different; instead of just one gap, there may be multiple gaps to open or close. Merging is a critical maneuver because the trail vehicle or platoon must temporarily move faster

than the lead platoon, and with a smaller distance gap, a sudden deceleration of the lead platoon may result in a collision at high speed. Thus, their relative velocities must be kept bounded to avoid dangerous collisions. An approach for platoon merging, splitting, and lane changing is presented in Frankel et al. (2007).

When the platooning objective is energy efficiency, the main question is whether the energy saved by the platoon exceeds the energy cost to form the platoon. A problem at a slightly higher level is the clustering of vehicles into platoons, based on their routes and departure and arrival times. An opportunity lies in the coordination of vehicle fleets: when origins, destinations, and time constraints are known in advance, a centralized planner can be set up, aggregating vehicles in platoons and thereby maximizing the overall fuel economy.

The idea of optimizing individual CAV dynamics using signal phase duration forecasts on a street with signalized intersections can be extended to platoons. An MPC framework for groups of CAVs with a decentralized approach, where every CAV only receives information from neighboring vehicles and traffic signals, is discussed in HomChaudhuri et al. (2017).

Summary and Future Directions

We conclude this short review about CAVs by listing some CAV research questions that are presently open and present a challenge:

- Platoon organization. Present platoon experiments are conducted under the assumption that addresses of all present CAVs and their places in the platoon are known. If this assumption is relaxed, how do CAVs find each other and agree on the platoon structure in multi-lane environment? This is especially difficult to do in a congested traffic.
- A proper detection or a correct estimation of a vehicle queue length at an urban intersection and a freeway on-ramp is an important component of effective traffic management as well as efficient operation of individual vehicles.

CAV coordination and performance optimization at road junctions are impossible without accurate and robust queue estimation. Queue estimation can be difficult, especially in the congested environment when traffic spillbacks to upstream junctions occur, and it becomes unclear where one queue ends and the other begins. Another challenge arises when multiple queues form on a single approach, e.g., when part of the traffic is queued up to make a left turn and the other part of the traffic waits for a straight movement.

- Solving the two problems above and adopting the related technology would enable the implementation of safe and efficient intersections for all connected road users, including cyclists and pedestrians. This implementation would include identification of travelers' blind zones and information exchange about agent presence in those blind zones, as well as signal optimization for groups of multimodal travelers – technologies that need to be developed.

Consensus of Complex Multi-agent Systems

Fabio Fagnani

Dipartimento di Scienze Matematiche ‘G.L. Lagrange’, Politecnico di Torino, Torino, Italy

Abstract

This article provides a broad overview of the basic elements of consensus dynamics. It describes the classical Perron-Frobenius theorem that provides the main theoretical tool to study the convergence properties of such systems. Classes of consensus models that are treated include simple random walks on grid-like graphs and in graphs with a bottleneck, consensus on graphs with intermittently randomly appearing edges between nodes (gossip models), and models with nodes that do not modify their state over time (stubborn agent models). Application to cooperative control, sensor networks, and socio-economic models are mentioned.

Keywords

Consensus dynamics · Multi-agent system · Gossip model · Stubborn agent

Introduction

Multi-agent systems constitute one of the fundamental paradigms of the science and technology of present century (Castellano et al. 2009; Strogatz 2003). The main idea is that of creating complex dynamical evolutions from the interactions of many simple units. Indeed such collective behaviors are quite evident in biological and social systems and were indeed considered in earlier times. More recently, the

digital revolution and the miniaturization in electronics have made possible the creation of man-made complex architectures of interconnected simple devices (computers, sensors, cameras). Moreover, the creation of Internet has opened totally new form of social and economic aggregation. This has strongly pushed toward a systematic and deep study of multi-agent dynamical systems. Mathematically they typically consist of a graph where each node possesses a state variable; states are coupled at the dynamical level through dependences determined by the edges in the graph. One of the challenging problems in the field of multi-agent systems is to analyze the emergence of complex collective phenomena from the interactions of the units which are typically quite simple. Complexity is typically the outcome of the topology and the nature of interconnections.

Consensus dynamics (also known as average dynamics) (Jadbabaie and Morse 2003; Carli et al. 2008) is one of the most popular and simplest multi-agent dynamics. One convenient way to introduce it is with the language of social sciences. Imagine that a number of independent units possess an information represented by a real number, for instance, such number can represent an opinion on a given fact. Units interact and change their opinion by averaging with the opinions of other units. Under certain assumptions this will lead the all community to converge to a consensus opinion which takes into consideration all the initial opinion of the agents. In social sciences, empiric evidences (Galton 1907) have shown how such aggregate opinion may give a very good estimation of unknown quantities: such phenomenon has been proposed in the literature as wisdom of crowds (Surowiecki 2007).

Consensus Dynamics, Graphs, and Stochastic Matrices

Mathematically, consensus dynamics are special linear dynamical systems of type

$$x(t+1) = Px(t) \quad (1)$$

where $x(t) \in \mathbb{R}^{\mathcal{V}}$ and $P \in \mathbb{R}^{\mathcal{V} \times \mathcal{V}}$ are *stochastic matrix* (e.g., a matrix with non-negative elements

such that every row sums to 1). $\mathcal{V}$ represents the finite set of units (agents) in the network, and $x(t)_v$ is to be interpreted as the state (opinion) of agent v at time t . Equation (1) implies that states of agents at time $t+1$ are convex combinations of the components of $x(t)$: this motivates the term averaging dynamics. Stochastic matrices owe their name to their use in probability: the term P_{vw} can be interpreted as the probability of making a jump in the graph from state v to state w . In this way you construct what is called a random walk on the graph $\mathcal{G}$.

The network structure is hidden in the non-zero pattern of P . Indeed we can associate to P a graph: $\mathcal{G}_P = (\mathcal{V}, \mathcal{E}_P)$ where the set of edges is given by $\mathcal{E}_P := \{(u, v) \in \mathcal{V} \times \mathcal{V} \mid P_{uv} > 0\}$. Elements in $\mathcal{E}_P$ represent the communication edges among the units: if $(u, v) \in \mathcal{E}_P$ it means that unit u has access to the state of unit v . Denote by $\mathbb{1} \in \mathbb{R}^{\mathcal{V}}$ the all 1's vector. Notice that $P\mathbb{1} = \mathbb{1}$: this shows that once the states of units are at consensus, they will no longer evolve. Will the dynamics always converge to a consensus point?

Remarkably, some of the key properties of P responsible for the transient and asymptotic behavior of the linear system (1) are determined by the connectivity properties of the underlying graph $\mathcal{G}_P$. We recall that, given two vertices $u, v \in \mathcal{V}$, a *path* (of length l) from u to v in $\mathcal{G}_P$ is any sequence of vertices $u = u_1, u_2, \dots, u_{l+1} = v$ such that $(u_i, u_{i+1}) \in \mathcal{E}_P$ for every $i = 1, \dots, l$. $\mathcal{G}_P$ is said to be *strongly connected* if for any pair of vertices $u \neq v$ in $\mathcal{V}$ there is a path in $\mathcal{G}_P$ connecting u to v . The *period* of a node u is defined as the greatest common divisor of the lengths of all closed paths from u to u . In strongly connected graph, all nodes have the same period, and the graph is called *aperiodic* if such a period is 1. If x is a vector, we will use the notation x^* to denote its transpose. If A is a finite set, $|A|$ denotes the number of elements in A . The following classical result holds true (Gantmacher 1959):

Theorem 1 (Perron-Frobenius) *Assume that $P \in \mathbb{R}^{\mathcal{V} \times \mathcal{V}}$ is such that $\mathcal{G}_P$ is strongly connected and aperiodic. Then:*

1. 1 is an algebraically simple eigenvalue of P .
2. There exists a (unique) probability vector $\pi \in \mathbb{R}^{\mathcal{V}}$ ($\pi_v > 0$ for all v and $\sum_v \pi_v = 1$) which is a left eigenvector for P , namely, $\pi^* P = \pi^*$.
3. All the remaining eigenvalues of P are of modulus strictly less than 1.

A straightforward linear algebra consequence of this result is that $P^t \rightarrow \mathbb{1}\pi^*$ for $t \rightarrow +\infty$. This yields

$$\lim_{t \rightarrow +\infty} x(t) = \lim_{t \rightarrow +\infty} P^t x(0) = \mathbb{1}(\pi^* x(0)) \quad (2)$$

All agents' states are thus converging to the common value $\pi^* x(0)$, called *consensus point* which is a convex combination of the initial states with weights given by the invariant probability components.

If π is the uniform vector (i.e., $\pi_v = |\mathcal{V}|^{-1}$ for all units v), the common asymptotic value is simply the arithmetic mean of the initial states: all agents equally contribute to the final common state. A special case when this happens is when P is symmetric. The distributed computation of the arithmetic mean is an important step to solve estimation problems for sensor networks. As a specific example, consider the situation where there are N sensors deployed in a certain area and each of them makes a noisy measurement of a physical quantity x . Let $y_v = x + \omega_v$ be the measure obtained by sensor v , where ω_v is a zero-mean Gaussian noise. It is well-known that if noises are independent and identically distributed, the optimal mean square estimator of the quantity x given the entire set of measurements $\{y_v\}$ is exactly given by $\hat{x} = N^{-1} \sum_v y_v$. Other fields of application is in the control of cooperative autonomous vehicles (Fax and Murray 2004; Jadbabaie and Morse 2003).

Basic linear algebra allows to study the rate of convergence to consensus. Indeed, if $\mathcal{G}_P$ is strongly connected and aperiodic, the matrix P has all its eigenvalues in the unit ball: 1 is the only eigenvalue with modulo equal to 1, while all the others have modulo strictly less than 1. If we denote by $\rho_2 < 1$ the largest modulo of such eigenvalues (different from 1), we can show that

$x(t) - \mathbb{1}(\pi^* x(0))$ converges exponentially to 0 as ρ_2^t . In the following we will briefly refer to ρ_2 as to the *second eigenvalue* of P .

Examples and Large-Scale Analysis

In this section we present some classical examples. Consider a strongly connected graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$. The *adjacency matrix* of $\mathcal{G}$ is a square matrix $A_{\mathcal{G}} \in \{0, 1\}^{\mathcal{V} \times \mathcal{V}}$ such that $(A_{\mathcal{G}})_{uv} = 1$ iff $(u, v) \in \mathcal{E}$. $\mathcal{G}$ is said to be symmetric (also called undirected in the literature) if $A_{\mathcal{G}}$ is symmetric. Given a symmetric graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$, we can consider the stochastic matrix P given by $P_{uv} = d_u^{-1}(A_{\mathcal{G}})_{uv}$ where $d_u = \sum_v (A_{\mathcal{G}})_{uv}$ is the *degree* of node u . P is called the *simple random walk* (SRW) on $\mathcal{G}$: each agent gives the same weight to the state of its neighbors. Clearly, $\mathcal{G}_P = \mathcal{G}$. A simple check shows that $\pi_v = d_v/|\mathcal{E}|$ is the invariant probability for P . The consensus point is given by

$$\pi^* x(0) = |\mathcal{E}|^{-1} \sum_v d_v x(0)_v$$

Each node contributes with its initial state to this consensus with a weight which is proportional to the degree of the node. Notice that the SRW P is symmetric iff the graph is regular, namely, all units have the same degree.

We now present a number of classical examples based on families of graphs with larger and larger number of nodes N . In this setting, particularly relevant is to understand the behavior of the second eigenvalue ρ_2 as a function of N . Typically, one considers $\epsilon > 0$ fixed and solves the equation $\rho_2^t = \epsilon$. The solution $\tau = (\ln \rho_2^{-1})^{-1} \ln \epsilon^{-1}$ will be called the *convergence time*: it essentially represents the time needed to shrink of a factor ϵ the distance to consensus. Dependence of ρ_2 on N will also yield that τ will be a function of N . In the sequel we will investigate such dependence for SRWs on certain classical families of graphs.

Example 1 (SRW on a complete graph) Consider the complete graph on the set $\mathcal{V}$: $K_{\mathcal{V}} := (\mathcal{V}, \mathcal{V} \times \mathcal{V})$

(also self-loops are present). The SRW on $K_{\mathcal{V}}$ is simply given by $P = N^{-1} \mathbb{1} \mathbb{1}^*$ where $N = |\mathcal{V}|$. Clearly, $\pi = N^{-1} \mathbb{1}$. Eigenvalues of P are 1 with multiplicity 1 and 0 with multiplicity $N - 1$. Therefore, $\rho_2 = 0$. Consensus in this case is achieved in just one step: $x(t) = N^{-1} \mathbb{1} \mathbb{1}^* x(0)$ for all $t \geq 1$.

Example 2 (SRW on a cycle graph) Consider the symmetric cycle graph $C_N = (\mathcal{V}, \mathcal{E})$ where $\mathcal{V} = \{0, \dots, N - 1\}$ and $\mathcal{E} = \{(v, v + 1), (v + 1, v)\}$ where sum is mod N . The graph C_N is clearly strongly connected and is also aperiodic if N is odd. The corresponding SRW P has eigenvalues

$$\lambda_k = \cos \frac{2\pi k}{N}$$

Therefore, if N is odd, the second eigenvalue is given by

$$\begin{aligned} \rho_2 &= \cos \frac{2\pi}{N} \\ &= 1 - 2\pi^2 \frac{1}{N^2} + o(N^{-2}) \quad \text{for } N \rightarrow +\infty \end{aligned} \quad (3)$$

while the corresponding convergence time is given by

$$\tau = (\ln \rho_2^{-1})^{-1} \ln \epsilon^{-1} \asymp N^2 \quad \text{for } N \rightarrow +\infty$$

Example 3 (SRW on toroidal grids) The toroidal d -grids C_n^d are formally obtained as a product of cycle graphs. The number of nodes is $N = n^d$. It can be shown that the convergence time behaves as

$$\tau \asymp N^{2/d} \quad \text{for } N \rightarrow +\infty$$

Convergence time exhibits a slower growth in N as the dimension d of the grid increases: this is intuitive since the increase in d determines a better connectivity of the graph and a consequently faster diffusion of information.

For a general stochastic matrix (even for SRW on general graphs), the computation of the second eigenvalue is not possible in closed form and can actually be also difficult from a numerical point of view. It is therefore important to develop

tools for efficient estimation. One of these is based on the concept of bottleneck: if a graph can be split into two loosely connected parts, then consensus dynamics will necessarily exhibit a slow convergence.

Formally, given a symmetric graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$ and a subset of nodes $S \subseteq \mathcal{V}$, define e_S as the number of edges with at least one node in S and e_{SS} as the number of edges with both nodes in S . The bottleneck of S in G is defined as $\Phi(S) = e_{SS}/e_S$. Finally, the *bottleneck ratio* of $\mathcal{G}$ is defined as

$$\Phi_* := \min_{S: e_S/e \leq 1/2} \Phi(S)$$

where $e = |\mathcal{E}|$ is the number of edges in the graph.

Let P be the SRW on $\mathcal{G}$ and let ρ_2 be its second eigenvalue. Then,

Proposition 1 (Cheeger bound Levin et al. 2008)

$$1 - \rho_2 \leq 2\Phi_*. \quad (4)$$

Example 4 (Graphs with a bottleneck) Consider two complete graphs with n nodes connected by just one edge. If S is the set of nodes of one of the two complete graphs, we obtain

$$\Phi(S) = \frac{1}{n^2 + 1}$$

Bound (4) implies that the convergence time is at least of the order of n^2 in spite of the fact that in each complete graph, convergence would be in finite time!

Other Models

The systems studied so far are based on the assumptions that units all behave the same – they share a common clock and update their state in a synchronous fashion. In this section, we discuss more general models.

Random Consensus Models

Regarding the assumption of synchronicity, it turns out to be unfeasible in many contexts. For

instance, in the opinion dynamics modelling, it is not realistic to assume that all interactions happen at the same time: agents are embedded in a physical continuous time, and interactions can be imagined to take place at random, for instance, in a pairwise fashion.

One of the most famous random consensus model is the gossip model. Fix a real number $q \in (0, 1)$ and a symmetric graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$. At every time instant t , an edge $(u, v) \in \mathcal{E}$ is activated with uniform probability $|\mathcal{E}|^{-1}$, and nodes u and v exchange their states and produce a new state according to the equations

$$\begin{aligned} x_u(t+1) &= (1-q)x_u(t) + qx_v(t) \\ x_v(t+1) &= qx_u(t) + (1-q)x_v(t) \end{aligned}$$

The states of the other units remain unchanged.

Will this dynamics lead to a consensus? If the same edge is activated at every time instant, clearly consensus will not be achieved. However, it can be shown that, with probability one, consensus will be reached (Boyd et al. 2006).

Consensus Dynamics with Stubborn Agents

In this chapter, we investigate consensus dynamics models where some of the agents do not modify their own state (stubborn agents). These systems are of interest in socioeconomic models (Acemoglu et al. 2013).

Consider a symmetric connected graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$. We assume a splitting $\mathcal{V} = \mathcal{S} \cup \mathcal{R}$ with the understanding that agents in $\mathcal{S}$ are *stubborn* agents not changing their state while those in $\mathcal{R}$ are *regular* agents whose state modifies in time according to a SRW consensus dynamics, namely,

$$x_u(t+1) = \frac{1}{d_u} \sum_{v \in \mathcal{V}} (A_{\mathcal{G}})_{uv} x_v(t), \quad \forall u \in \mathcal{R}$$

By assembling the state of the regular and of the stubborn agents in vectors denoted, respectively, as $x^{\mathcal{R}}(t)$ and $x^{\mathcal{S}}(t)$, dynamics can be recasted in matrix form as

$$\begin{aligned} x^{\mathcal{R}}(t+1) &= Q^{11} x^{\mathcal{R}}(t) + Q^{12} x^{\mathcal{S}}(t) \\ x^{\mathcal{S}}(t+1) &= x^{\mathcal{S}}(t) \end{aligned} \quad (5)$$

It can be proven that Q^{11} is asymptotically stable ($(Q^{11})^t \rightarrow 0$). Henceforth, $x^{\mathcal{R}}(t) \rightarrow x^{\mathcal{R}}(\infty)$ for $t \rightarrow +\infty$ with the limit opinions satisfying the relation

$$x^{\mathcal{R}}(\infty) = Q^{11} x^{\mathcal{R}}(\infty) + Q^{12} x^{\mathcal{S}}(0) \quad (6)$$

If we define $\mathcal{E} := (I - Q^{11})^{-1} Q^{12}$, we can write $x^{\mathcal{R}}(\infty) = \mathcal{E} x^{\mathcal{S}}(0)$. It is easy to see that $\mathcal{E}$ has non-negative elements and that $\sum_s \mathcal{E}_{us} = 1$ for all $u \in \mathcal{R}$: asymptotic opinions of regular agents are thus convex combinations of the opinions of stubborn agents. If all stubborn agents are in the same state x , then consensus is reached by all agents in the point x . However, typically, consensus is not reached in such a system: we will discuss an example below.

There is a useful alternative interpretation of the asymptotic opinions. Interpreting the graph $\mathcal{G}$ as an electrical circuit where edges are unit resistors, relation (6) can be seen as a Laplace-type equation on the graph $\mathcal{G}$ with boundary conditions given by assigning the voltage $x^{\mathcal{S}}(0)$ to the stubborn agents. In this way $x^{\mathcal{R}}(\infty)$ can be interpreted as the vector of voltages of the regular agents when stubborn agents have fixed voltage $x^{\mathcal{S}}(0)$. Thanks to the electrical analogy, we can compute the asymptotic opinion of the agents by computing the voltages in the various nodes in the graph. We propose a concrete application in the following example:

Example 5 (Stubborn agents in a line graph)

Consider the line graph $L_N = (\mathcal{V}, \mathcal{E})$ where $\mathcal{V} = \{1, 2, \dots, N\}$ and where $\mathcal{E} = \{(u, u+1), (u+1, u) \mid u = 1, \dots, N-1\}$. Assume that $\mathcal{S} = \{1, N\}$ and $\mathcal{R} = \mathcal{V} \setminus \mathcal{S}$. Consider the graph as an electrical circuit. Replacing the line with a single edge connecting 1 and N having resistance $N-1$ and applying Ohm's law, we obtain that the current flowing from 1 to N is equal to $\Phi = (N-1)^{-1} [x_N^{\mathcal{S}}(0) - x_1^{\mathcal{S}}(0)]$. If we now fix an arbitrary node $v \in \mathcal{V}$ and applying again

the same arguments in the part of graph from 1 to v , we obtain that the voltage at v , $x_v^{\mathcal{R}}(\infty)$ satisfies the relation $x_v^{\mathcal{R}}(\infty) - x_1^{\mathcal{S}}(0) = \Phi(v-1)$. We thus obtain

$$x_v^{\mathcal{R}}(\infty) = x_1^{\mathcal{S}}(0) + \frac{v-1}{N-1} [x_N^{\mathcal{S}}(0) - x_1^{\mathcal{S}}(0)].$$

In Acemoglu et al. (2013) further examples are discussed showing how, because of the topology of the graph, different asymptotic configurations may show up. While in graphs presenting bottlenecks polarization phenomena can be recorded, in graphs where the convergence rate is low, there will be a typical asymptotic opinion shared by most of the regular agents.

Summary and Future Directions

We have presented an overview of linear consensus multiagent dynamics over general networks encompassing deterministic and random models. We have also briefly analyzed models in the presence of stubborn agents.

A number of other directions, not considered in the present paper, are worth of analysis. Among them are inferential models in the presence of heterogeneous agents, second-order models, nonlinear models.

Control and Optimization of Batch Processes

Dominique Bonvin
Laboratoire d'Automatique, École
Polytechnique Fédérale de Lausanne (EPFL),
1015 Lausanne, Switzerland

Abstract

A batch process is characterized by the repetition of time-varying operations of finite duration. Due to the repetition, there are two independent “time” variables, namely, the run time during a batch and the batch counter. Accordingly, the control and optimization objectives can be defined for a given batch or over several batches. This entry describes the various control and optimization strategies available for the operation of batch processes. These include conventional feedback control, predictive control, iterative learning control,

and run-to-run control on the one hand and model-based repeated optimization and model-free self-optimizing schemes on the other.

Keywords

Batch control · Batch process optimization · Dynamic optimization · Iterative learning control · Run-to-run control · Run-to-run optimization

Introduction

Batch processing is widely used in the manufacturing of goods and commodity products, in particular in the chemical, pharmaceutical, and food industries. These industries account for several billion US dollars in annual sales. Batch operation differs significantly from continuous operation. While in continuous operation the process is maintained at an economically desirable operating point, the process evolves continuously from an initial to a final time in batch processing. In the chemical industry, for example, since the design of a continuous plant requires substantial engineering effort, continuous operation is rarely used for low-volume production. Discontinuous operations can be of the batch or semi-batch type. In batch operations, the products to be processed are loaded in a vessel and processed without material addition or removal. This operation permits more flexibility than continuous operation by allowing adjustment of the operating conditions and the final time. Additional flexibility is available in semi-batch operations, where products are continuously added by adjusting the feed rate profile. We use the term batch process to include semi-batch processes.

Batch processes dealing with reaction and separation operations include reaction, distillation, absorption, extraction, adsorption, chromatography, crystallization, drying, filtration, and centrifugation. The operation of batch processes involves recipes developed in the laboratory. A sequence of operations is performed in a prespecified order in specialized process

equipment, yielding a fixed amount of product. The sequence of tasks to be carried out on each piece of equipment, such as heating, cooling, reaction, distillation, crystallization, and drying, is predefined. The desired production volume is then achieved by repeating the processing steps on a predetermined schedule.

The main characteristics of batch process operations include the absence of steady state, the presence of constraints, and the repetitive nature. These characteristics bring both challenges and opportunities to the operation of batch processes (Bonvin 1998). The challenges are related to the fact that the available models are often poor and incomplete, especially since they need to represent a wider range of operating conditions than in the case of continuous processes. Furthermore, although product quality must be controlled, this variable is usually not available online but only at run end. On the other hand, opportunities stem from the fact that industrial chemical processes are often slow, which facilitates larger sampling periods and extensive online computations. In addition, the repetitive nature of batch processes opens the way to run-to-run process improvement (Bonvin et al. 2006). More information on batch processes and their operation can be found in Seborg et al. (2004) and Nagy and Braatz (2003). Next, we will successively address the control and the optimization of batch processes.

Control of Batch Processes

Control of batch processes differs from control of continuous processes in two main ways. First, since batch processes have no steady-state operating point, at least some of the set points are time-varying profiles. Second, batch processes are repeated over time and are characterized by two independent variables, the run time t and the run counter k . The independent variable k provides additional degrees of freedom for meeting the control objectives when these objectives do not necessarily have to be completed in a single batch but can be distributed over several successive batches. This situation brings into

Implementation aspect	Control objectives	
	Run-time references $y_{\text{ref}}(t)$ or $y_{\text{ref}}[0, t_f]$	Run-end references z_{ref}
Online (within-run)	1 Feedback control $u_k(t) \rightarrow y_k(t) \rightarrow y_k[0, t_f]$ $\uparrow$ FBC	2 Predictive control $u_k(t) \rightarrow z_{\text{pred},k}(t)$ $\uparrow$ MPC
Iterative (run-to-run)	3 Iterative learning control $u_k[0, t_f] \rightarrow y_k[0, t_f]$ $\uparrow$ ILC with run delay	4 Run-to-run control $\mathcal{U}(\pi_k) = u_k[0, t_f] \rightarrow z_k$ $\uparrow$ R2R with run delay

Control and Optimization of Batch Processes, Fig. 1

Control strategies for batch processes. The strategies are classified according to the control objectives (horizontal division) and the implementation aspect (vertical division). Each objective can be met either online or iteratively over several batches depending on the type of measurements available. u_k represents the input vector for the

k th batch, $u_k[0, t_f]$ the corresponding input trajectories, $y_k(t)$ the run-time outputs measured online, and z_k the run-end outputs available at the final time. FBC stands for “feedback control,” MPC for “model predictive control,” ILC for “iterative learning control,” and R2R for “run-to-run control”

focus the concept of run-end outputs, which need to be controlled but are only available at the completion of the batch. The most common run-end output is product quality. Consequently, the control of batch processes encompasses four different strategies (Fig. 1):

1. *Online control of run-time outputs.* This control approach is similar to that used in continuous processing. However, although some controlled variables, such as temperature in isothermal operation, remain constant, the key process characteristics, such as process gain and time constants, can vary considerably because operation occurs along state trajectories rather than at a steady-state operating point. Hence, adaptation in run time t is needed to handle the expected variations. Feedback control is implemented using PID techniques or more sophisticated alternatives (Seborg et al. 2004).
2. *Online control of run-end outputs.* In this case it is necessary to predict the run-end outputs z based on measurements of the run-time outputs y . Model predictive control (MPC) is well suited to this task (Nagy and Braatz 2003). However, the process models available

for prediction are often simplified and thus of limited accuracy.

3. *Iterative control of run-time outputs.* The manipulated variable profiles can be generated using iterative learning control (ILC), which exploits information from previous runs (Moore 1993). This strategy exhibits the limitations of open-loop control with respect to the current run, in particular the fact that there is no feedback correction for run-time disturbances. Nevertheless, this scheme is useful for generating a time-varying feedforward input term.
4. *Iterative control of run-end outputs.* In this case the input profiles are parameterized as $u_k[0, t_f] = \mathcal{U}(\pi_k)$ using the input parameters π_k . The batch process is thus seen as a static map between the input parameters π_k and the run-end outputs z_k (Francois et al. 2005).

It is also possible to combine online and run-to-run control for both y and z . However, in such a combined scheme, care must be taken so that the online and run-to-run corrective actions do not oppose each other. Stability during run time and convergence in run index must be guaranteed (Srinivasan and Bonvin 2007a).

Optimization of Batch Processes

The process variables undergo significant changes during batch operation. Hence, the major objective in batch operations is not to keep the system at optimal constant set points but rather to determine input profiles that optimize an objective function expressing the system performance.

Problem Formulation

A typical optimization problem in the context of batch processes is

$$\min_{u_k[0,t_f]} J_k = \phi(x_k(t_f)) + \int_0^{t_f} L(x_k(t), u_k(t), t) dt \quad (1)$$

subject to

$$\dot{x}_k(t) = F(x_k(t), u_k(t)), \quad x_k(0) = x_{k,0} \quad (2)$$

$$S(x_k(t), u_k(t)) \leq 0, \quad T(x_k(t_f)) \leq 0, \quad (3)$$

where x represents the state vector, J the scalar cost to be minimized, S the run-time constraints, T the run-end constraints, and t_f the final time.

In constrained optimal control problems, the solution often lies on the boundary of the feasible region. Batch processes involve run-time constraints on inputs and states as well as run-end constraints.

Optimization Strategies

As can be seen from the cost objective (1), optimization requires information about the complete run and thus cannot be implemented in real time using only online measurements. Some information regarding the future of the run is needed in the form of either a process model capable of prediction or measurements from previous runs. Accordingly, measurement-based optimization methods can be classified depending on whether or not a process model is used explicitly for implementation, as illustrated in Fig. 2 and discussed next:

1. *Online explicit optimization.* This approach is similar to model predictive control (Nagy and Braatz 2003). Optimization uses a process model explicitly and is repeated whenever a new set of measurements becomes available. This scheme involves two steps, namely, updating the initial conditions for the subsequent optimization (and optionally the param-

Implementation aspect	Use of process model	
	Explicit optimization (with process model)	Implicit optimization (without process model)
Online (within-run)	1 Repeated online optimization $y_k[0,t] \xrightarrow{\text{EST}} \hat{x}_k(t) \xrightarrow{\text{OPT}} u_k^*[t,t_f]$ 	2 Online input update using measurements $y_k(t) \xrightarrow{\text{Approx. of opt. solution}} u_k^*(t)$ $y_k[0,t] \xrightarrow{\text{NCO prediction}} \text{NCO} \rightarrow u_k^*(t)$
Iterative (run-to-run)	3 Repeated run-to-run optimization $y_k[0,t_f] \xrightarrow{\text{IDENT}} \hat{\theta}_k \xrightarrow{\text{OPT}} u_{k+1}^*[0,t_f]$ 	4 Run-to-run input update using measurements $y_k[0,t_f] \xrightarrow{\text{NCO evaluation}} \text{NCO} \rightarrow u_{k+1}^*[0,t_f]$

Control and Optimization of Batch Processes, Fig. 2 Optimization strategies for batch processes. The strategies are classified according to whether or not a process model is used for implementation (horizontal division). Furthermore, each class can be implemented either online

or iteratively over several runs (vertical division). EST stands for “estimation,” IDENT for “identification,” OPT for “optimization,” and NCO for “necessary conditions of optimality”

eters of the process model) and numerical optimization based on the updated process model (Abel et al. 2000). Since both steps are repeated as measurements become available, the procedure is also referred to as repeated online optimization. The weakness of this method is its reliance on the model; if the model is not updated, its accuracy plays a crucial role. However, when the model is updated, there is a conflict between parameter identification and optimization since parameter identification requires persistency of excitation, that is, the inputs must be sufficiently varied to uncover the unknown parameters, a condition that is usually not satisfied when near-optimal inputs are applied. Note that, instead of computing the input $u_k^*[t, t_f]$, it is also possible to use a receding horizon and compute only $u_k^*[t, t + T]$, with T the control horizon (Abel et al. 2000).

2. *Online implicit optimization.* In this scenario, measurements are used to update the inputs directly, that is, without the intermediary of a process model. Two classes of techniques can be identified. In the first class, an update law that approximates the optimal solution is sought. For example, a neural network is trained with data corresponding to optimal behavior for various uncertainty realizations and used to update the inputs (Rahman and Palanki 1996). The second class of techniques relies on transforming the optimization problem into a control problem that enforces the necessary conditions of optimality (NCO) (Srinivasan and Bonvin 2007b). The NCO involve constraints that need to be made active and sensitivities that need to be pushed to zero. Since some of these NCO are evaluated at run time and others at run end, the control problem involves both run-time and run-end outputs. The main issue is the measurement or estimation of the controlled variables, that is, the constraints and sensitivities that constitute the NCO.
3. *Iterative explicit optimization.* The steps followed in run-to-run explicit optimization are the same as in online explicit optimization. However, there is substantially more data

available at the end of the run as well as sufficient computational time to refine the model by updating its parameters and, if needed, its structure. Furthermore, data from previous runs can be collected for model update (Rastogi et al. 1992). As with online explicit optimization, this approach suffers from the conflict between estimation and optimization.

4. *Iterative implicit optimization.* In this scenario, the optimization problem is transformed into a control problem, for which the control approaches in the second row of Fig. 1 are used to meet the run-time and run-end objectives (Francois et al. 2005). The approach, which is conceptually simple, might be experimentally expensive since it relies more on data.

These complementary measurement-based optimization strategies can be combined by implementing some aspects of the optimization online and others on a run-to-run basis. For instance, in explicit schemes, the states can be estimated online, while the model parameters can be estimated on a run-to-run basis. Similarly, in implicit optimization, approximate update laws can be implemented online, leaving the responsibility for satisfying terminal constraints and sensitivities to run-to-run controllers.

Summary and Future Directions

Batch processing presents several challenges. Since there is little time for developing appropriate dynamic models, there is a need for improved data-driven control and optimization approaches. These approaches require the availability of online concentration-specific measurements such as chromatographic and spectroscopic sensors, which are not yet readily available in production.

Technically, the main operational difficulty in batch process improvement lies in the presence of run-end outputs such as final quality, which cannot be measured during the run. Although model-based solutions are available, process models in the batch area tend to be poor. On

the other hand, measurement-based optimization for a given batch faces the challenge of having to know about the future to act during the batch. Consequently, the main research push is in the area of measurement-based optimization and the use of data from both the current and previous batches for control and optimization purposes.

Control Applications in Audio Reproduction

Yutaka Yamamoto
Graduate School of Informatics, Kyoto
University, Kyoto, Japan

Abstract

This entry gives a brief overview of the recent developments in audio sound reproduction via modern sampled-data control theory. We first review basics in the current sound processing technology and then proceed to the new idea derived from sampled-data control theory, which is different from the conventional Shannon paradigm based on the perfect band-limiting hypothesis. The hybrid nature of sampled-data systems provides an optimal platform for dealing with signal processing where the ultimate objective is to reconstruct the original analog signal one started with. After discussing some fundamental problems in the Shannon paradigm, we give our basic problem formulation that can be solved using modern sampled-data control theory. Examples are given to illustrate the results.

Keywords

Digital signal processing · Multirate signal processing · Sampled-data control · Sampling theorem · Sound reconstruction

Introduction: Status Quo

Consider the problem of reproducing sounds from recorded media such as compact discs. The current CD format is recorded at the sampling frequency 44.1 kHz. It is commonly claimed that the highest frequency for human audibility is

Control Applications in Audio Reproduction,
Fig. 1 Upsampler for $M = 2$

20 kHz, whereas the upper bound of reproduction in this format is believed to be the half of 44.1 kHz, i.e., 22.05 kHz, and hence, this format should have about 10 % margin against the alleged audible limit of 20 kHz.

CD players of early days used to process such digital signals with the simple zero-order hold at this frequency, followed by an analog low-pass filter. This process requires a sharp low-pass characteristic to cut out unnecessary high frequency beyond 20 kHz. However, a sharp cut-off low-pass characteristic inevitably requires a high-order filter which in turn introduces a large amount of phase shift distortion around the cutoff frequency.

To circumvent this defect, the idea of an oversampling DA converter that is realized by the combination of a digital filter and a low-order analog filter was introduced (Zelniker and Taylor 1994). This is based on the following principle:

Let $\{f(nh)\}_{n=-\infty}^{\infty}$ be a discrete-time signal obtained from a continuous-time signal $f(\cdot)$ by sampling it with sampling period h . The *upsampler* appends the value 0, $M - 1$ times, between two adjacent sampling points:

$$(\uparrow Mw)[k] := \begin{cases} w(\ell), & k = M\ell \\ 0, & \text{elsewhere.} \end{cases} \quad (1)$$

See Fig. 1 for the case $M = 2$. This has the effect of making the unit operational time M times faster.

The bandwidth will also be expanded by M times and the *Nyquist frequency* (i.e., half the sampling frequency) becomes $M\pi/h$ [rad/sec]. As we see in the next section, the Nyquist frequency is often regarded as the true bandwidth of the discrete-time signal $\{f(nh)\}_{n=-\infty}^{\infty}$. But this upsampling process just inserts zeros between

sampling points, and the real information contents (the true bandwidth) is not really expanded. As a result, the copy of the frequency content for $[0, \pi/h)$ appears as a mirror image repeatedly over the frequency range above π/h . This distortion is called *imaging*. In order to avoid the effect of such mirrored frequency components, one often truncates the frequency components beyond the (original) Nyquist frequency via a digital low-pass filter that has a sharp roll-off characteristic. One can then complete the digital to analog (DA) conversion process by postposing a slowly decaying analog filter. This is the idea of an *oversampling DA converter* (Zelniker and Taylor 1994). The advantage here is that by allowing a much wider frequency range, the final analog filter can be a low-order filter and hence yields a relatively small amount of phase distortion supported in part by the linear-phase characteristic endowed on the digital filter preceding it.

Signal Reconstruction Problem

As before, consider the sampled discrete-time signal $\{f(nh)\}_{n=-\infty}^{\infty}$ obtained from a continuous-time signal f . The main question is how we can recover the original continuous-time signal $f(\cdot)$ from sampled data. This is clearly an ill-posed problem without any assumption on f because there are infinitely many functions that can match the sampled data $\{f(nh)\}_{n=-\infty}^{\infty}$. Hence, one has to impose a reasonable a priori assumption on f to sensibly discuss this problem.

The following sampling theorem gives one answer to this question:

Theorem 1 Suppose that the signal $f \in L^2$ is perfectly band-limited, in the sense that there exists $\omega_0 \leq \pi/h$ such that the Fourier transform

$\hat{f}$ of f satisfies

$$\hat{f}(\omega) = 0, \quad |\omega| \geq \omega_0, \quad (2)$$

Then

$$f(t) = \sum_{n=-\infty}^{\infty} f(nh) \frac{\sin \pi(t/h - n)}{\pi(t/h - n)}. \quad (3)$$

This theorem states that if the signal f does not contain any high-frequency components beyond the *Nyquist frequency* π/h , then the original signal f can be uniquely reconstructed from its sampled-data $\{f(nh)\}_{n=-\infty}^{\infty}$. On the other hand, if this assumption does not hold, then the result does not necessarily hold. This is easy to see via a schematic representation in Fig. 2.

If we sample the sinusoid in the upper figure in Fig. 2, these sampled values would turn out to be compatible with another sinusoid with much lower frequency as the lower figure shows. In other words, this sampling period does not have enough resolution to distinguish these two sinusoids. The maximum frequency below where there does not occur such a phenomenon is the Nyquist frequency. The sampling theorem above asserts that it is half of the sampling frequency $2\pi/h$, that is, π/h [rad/sec]. In other words, if we can assume that the original signal contains no frequency components beyond the Nyquist frequency, then one can uniquely reconstruct the original analog signal f from its sampled-

data $\{f(nh)\}_{n=-\infty}^{\infty}$. On the other hand, if this assumption does not hold, the distortion depicted in Fig. 2 occurs; this is called *aliasing*.

This is the content of the sampling theorem. It has been widely accepted as the basis for digital signal processing that bridges analog to digital. Concrete applications such as CD, MP3, and digital images are based on this principle in one way or another.

Difficulties

However, this paradigm (hereafter the *Shannon paradigm*) of the perfect band-limiting hypothesis and the resulting sampling theorem renders several difficulties as follows:

- The reconstruction formula (3) is not causal, i.e., one needs future sampled values to reconstruct the present value $f(t)$. One can remedy this defect by allowing a certain amount of delay in reconstruction, but this delay can depend on how fast the formula converges.
- This formula is known to decay slowly; that is, we need many terms to approximate if we use this formula as it is.
- The perfect band-limiting hypothesis is hardly satisfied in reality. For example, for CDs, the Nyquist frequency is 22.05 kHz, and the energy distribution of real sounds often extends way over 20 kHz.

Control Applications in Audio Reproduction,
Fig. 2 Aliasing

Control Applications in Audio Reproduction,

Fig. 3 Ringing due to the Gibbs phenomenon

- To remedy this, one often introduces a band-limiting low-pass filter, but it can introduce distortions due to the Gibbs phenomenon well-known in Fourier analysis. A sharp truncation in the frequency domain yields such a ringing effect. See Fig. 3.

In view of such drawbacks, there has been revived interest in the extension of the sampling theorem in various forms since the 1990s. There is by now a stream of papers that aim at studying signal reconstruction under the assumption of nonideal signal acquisition devices; an excellent survey is given in Unser (2000). In this research framework, the incoming signal is supposed to be acquired through a nonideal analog filter (acquisition device) and sampled, and then the reconstruction process attempts to recover the original signal. The idea is to place the problem into the framework of the (orthogonal or oblique) projection theorem in a Hilbert space (usually L^2) and then project the signal space to the subspace generated by the shifted reconstruction functions. It is often required that the process gives a *consistent* result, i.e., if we subject the reconstructed signal to the whole process again, it should yield the same sampled values from which it was reconstructed (Unser and Aldroubi 1994).

In what follows, we take a similar viewpoint, that is, the incoming signals are acquired through a nonideal filter but develop a methodology different from the projection method, relying on sampled-data control theory.

The Signal Class

We have seen that the perfect band-limiting hypothesis is restrictive. Even if we adopt it, it is a fairly crude model for analog signals to allow for a more elaborate study.

Let us now pose the question: *What class of functions should we process in such systems?*

Consider the situation where one plays a musical instrument, say, a guitar. A guitar naturally has a frequency characteristic. When one picks a string, it produces a certain tone along with its harmonics, as well as a characteristic transient response. All these are governed by a certain frequency decay curve, demanded by the physical characteristics of the guitar. Let us suppose that such a frequency decay is governed by a rational transfer function $F(s)$ and it is driven by varied exogenous inputs.

Consider Fig. 4. The exogenous analog signal $w_c \in L^2$ is applied to the analog filter $F(s)$.

Control Applications in Audio Reproduction, Fig. 4 Error system for sampled-data design

This $F(s)$ is not an ideal filter, and hence its bandwidth is not restricted to below the Nyquist frequency. The signal w_c drives $F(s)$ to produce the target analog signal y_c , which should be the signal to be reconstructed. It is then sampled by sampler S_h and becomes the recorded or transmitted digital signal y_d . The objective here is to reconstruct the target analog signal y_c out of this sampled signal y_d . In order to recover the frequency components beyond the Nyquist frequency, one needs a faster sampling period, so we insert the upsampler $\uparrow L$ to make the sampling period h/L . This upsampled signal is processed by digital filter $K(z)$ and then becomes a continuous-time signal again by going through the hold device $\mathcal{H}_{h/L}$. It will then be processed by analog filter $P(s)$ to be smoothed out. The obtained signal is then compared with delayed analog signal $y_c(t - mh)$ to form the delayed error signal e_c . The objective is then to make this error e_c as small as possible. The reason for allowing delay e^{-mhs} is to accommodate certain processing delays. This is the idea of the block diagram Fig. 4.

The performance index we minimize is the induced norm of the transfer operator T_{ew} from w_c to e_c :

$$\|T_{ew}\|_\infty := \sup_{w_c \neq 0} \frac{\|e_c\|_2}{\|w_c\|_2}. \quad (4)$$

This is the H^∞ norm of the sampled-data control system Fig. 4. Our objective is then to solve the following problem:

Filter Design Problem

Suppose we are given the system specified by Fig. 4. For a given performance level $\gamma > 0$, find a filter $K(z)$ such that

$$\|T_{ew}\|_\infty < \gamma.$$

This is a sampled-data H^∞ (sub-)optimal control problem. It can be solved by using the standard solution method for sampled-data control systems (Chen and Francis 1995a; Yamamoto 1999; Yamamoto and Nagahara 2017; Yamamoto et al. 2012). The only anomaly here is that the system in Fig. 4 contains a delay element e^{-mhs} which is infinite dimensional. However, by suitably approximating this delay by successive series of shift registers, one can convert the problem to an appropriate finite-dimensional discrete-time problem (Yamamoto et al. 1999, 2002, 2012).

This problem setting has the following features:

1. One can optimize the continuous-time performance under the constraint of discrete-time filters.
2. By setting the class of input functions as L^2 functions band-limited by $F(s)$, one can capture the continuous-time error signal e_c and its worst-case norm in the sense of (4).

The first feature is due to sampled-data control theory. A great advantage of sampled-data control theory is that it allows the mixture of continuous- and discrete-time components. This is in marked contrast to the Shannon paradigm where continuous-time performance is really demanded by the artificial perfect band-limiting hypothesis.

The second feature is an advantage due to H^∞ control theory. Naturally, we cannot have an access to each *individual* error signal e_c , but we can still control the *overall performance* from w_c to e_c in terms of the H^∞ norm that guarantees the

Control Applications in Audio Reproduction,

Fig. 5 Response of the proposed sampled-data filter against a rectangular wave

worst-case performance. This is in clear contrast with the classical case where only a representative response, e.g., impulse response in the case of H^2 , is targeted. Furthermore, since we can control the continuous-time performance of the worst-case error signal, the present method can indeed minimize (continuous-time) phase errors. This is an advantage usually not possible with conventional methods since they mainly discuss the gain characteristics of the designed filters only. By the very property of minimizing the H^∞ norm of the *continuous-time error signal* e_c , the present method can even control the phase errors and yield much less phase distortion even around the cutoff frequency.

Figure 5 shows the response of the proposed sampled-data filter against a rectangular wave, with a suitable first- or second-order analog filter $F(s)$; see Yamamoto et al. (2012) for more details. Unlike Fig. 3, the overshoot is controlled to be minimum.

The present method has been patented (Yamamoto 2006; Yamamoto and Nagahara 2006; Fujiyama et al. 2008) and implemented into sound processing LSI chips as a core technology by Sanyo Semiconductor and successfully used in mobile phones, digital voice

recorders, and MP3 players; their cumulative production has exceeded 70 million units as of the end of 2017.

Summary and Future Directions

We have presented basic ideas of new signal processing theory derived from sampled-data control theory. The theory presents advantages over conventional projection methods, whether based on the perfect band-limiting hypothesis or not.

The application of sampled-data control theory to digital signal processing was first made by Chen and Francis (1995b) with performance measure in the discrete-time domain; see also Hassibi et al. (2006). The present author and his group have pursued the idea presented in this article since 1996 (Khargonekar and Yamamoto 1996). See Yamamoto et al. (2012) and references therein. For the background of sampled-data control theory, consult, e.g., Chen and Francis (1995a), Yamamoto (1999), and Yamamoto and Nagahara (2017).

The same philosophy of emphasizing the importance of analog performance was proposed and pursued recently by Unser and co-workers

(1994), Unser (2005), and Eldar and Dvorkind (2006). The crucial difference is that they rely on L^2/H^2 type optimization and orthogonal or oblique projections, which are very different from our method here. In particular, such projection methods can behave poorly for signals outside the projected space. The response shown in Fig. 3 is a typical such example.

Applications to image processing are discussed in Yamamoto et al. (2012). An application to delta-sigma DA converters is studied in Nagahara and Yamamoto (2012a); see also Nagahara and Yamamoto (2012b) for a design with non-integer delays that is effective in pitch shifting. The reader is also referred to Yamamoto et al. (2017, 2018) for filter designs involving generalized sampling or with compactly supported acquisition devices. Again, the crux of the idea is to assume a signal generator model and then design an optimal filter in the sense of Fig. 4 or a similar diagram with the same idea. This idea should be applicable to a much wider class of problems in signal processing and should prove to have more impact.

Some processed examples of still and moving images are downloadable from the site: <https://sites.google.com/site/yutakayamamotoen/>

For the sampling theorem, see Shannon (1949), Unser (2000), and Zayed (1996), for example. Note, however, that Shannon himself (1949) did not claim originality on this theorem; hence, it is misleading to attribute this theorem solely to Shannon. See Unser (2000) and Zayed (1996) for some historical accounts. For a general background in signal processing, Vetterli et al. (2013) is useful.

Control for Precision Mechatronics

Tom Oomen
Department of Mechanical Engineering,
Eindhoven University of Technology,
Eindhoven, The Netherlands

Abstract

Motion systems are a key enabling technology in manufacturing machines and scientific instruments. Indeed, these motion systems perform the positioning with high speed and accuracy, where typical requirements are in the micrometer or even nanometer range. This is achieved through a mechatronic system design, which includes actuators, sensors, mechanics, and control. The aim of this entry is to outline advanced motion control for precision mechatronics. Both feedback and feedforward control are covered. Their specific designs are heavily influenced by considerations regarding efficient and accurate modeling techniques. Extensions to complex multivariable systems are outlined, as well as challenges induced by envisaged future application requirements.

Keywords

Mechatronics · Feedback control · Feedforward control · Learning control · System identification

Introduction

Manufacturing machines and scientific instruments have a key role in our society, and the role of these mechatronic systems will increase in the future. For instance, future developments in manufacturing machines as used in lithographic integrated circuit (IC) production will enable ubiquitous computing power for emerging fields in communication, medical equipment, transportation, etc. In fact, Moore's law, dictating computational progress, is determined by wafer scanner technology. Ongoing developments in printing systems are foreseen to lead to additive manufacturing techniques that enable the design of new products with a functionality that is unimaginable in classical production techniques. Highly accurate scientific instruments, including microscopy, will facilitate scientific discoveries in nanotechnology and biotechnology. Increasingly large telescopes will spur deep space exploration. Finally, medical equipment, for instance, computerized tomography (CT) scanners, will enable improved medical treatments. To keep up with performance requirements imposed by societal demands, future machines must achieve unprecedented performance.

Motion systems are key subsystems essential for meeting future requirements. These mechatronic subsystems are responsible for the motion that positions the product in the machine, e.g., the wafer in lithography, the substrate in printing, the sample in microscopy, the mirror alignment in telescopes and lithographic optics, and the detector in CT scanners. Future machines, e.g., in lithography, must achieve an extreme accuracy of 0.1 nm over a range of 1 m, exceeding a 1 billion ratio, with speeds up to $1 \frac{\text{m}}{\text{s}}$ and accelerations of $100 \frac{\text{m}}{\text{s}^2}$.

Control is an essential aspect in such motion systems (Ohnishi et al 1996), (Lee and Tomizuka 1996), (Steinbuch and Norg 1998), Devasia et al (2007). Indeed, mechatronic system design involves many aspects, including actuators, mechanics, and sensors (Munnig Schmidt et al 2011). Despite a very large variety in designs and applications, motion control is remarkably similar from system to system.

Motion Systems

Mechatronic systems typically consist of actuators, mechanics, and sensors. These actuators generate a force or a torque for example, while the sensors can measure position, rotation, etc. The dynamics of such systems are typically dominated by the mechanics, with sensing and actuation assumed to be perfect because their dynamics are much faster and more precise than the mechanics. As a result Gawronski (2004),

$$y(s) = \left(\underbrace{\sum_{i=1}^{n_{RB}} \frac{c_i b_i^T}{s^2}}_{\text{rigid-body modes}} + \underbrace{\sum_{i=n_{RB}+1}^{n_s} \frac{c_i b_i^T}{s^2 + 2\zeta_i \omega_i s + \omega_i^2}}_{\text{flexible modes}} \right) u(s), \quad (1)$$

where y is the output position, u is the actuator input, n_{RB} is the number of rigid-body modes, the vectors $c_i \in \mathbb{R}^{n_y}$ and $b_i \in \mathbb{R}^{n_u}$ are associated with the mode shapes, and $\zeta_i, \omega_i \in \mathbb{R}_+$. Here, $n_s \in \mathbb{N}$ may be very large and even infinite. Also, s is a complex indeterminate due to the Laplace transform. Note that in (1), it is assumed that the rigid-body modes are not suspended, i.e., the term $\frac{1}{s^2}$ relates to Newton's second law. In the case of suspended rigid-body modes, e.g., in case of flexures as in Fleming and Leang (2014), (1) can directly be extended.

The desktop printer in Fig. 1 is a low-complexity example that satisfies (1). In particular, in Fig. 2, the Bode plot of the transfer function in (1) is shown, together with a measurement of the real system. A single rigid-body mode and a single flexible mode can clearly be observed. Note that both (1) and the Bode plot inherently assume linear dynamics; friction effects that are present in the printer are further investigated in a later section.

Control Goal and Architecture

The main goal in motion control is a servo task: let the output y follow a prespecified reference r . This is typically achieved through the control architecture in Fig. 3. Assuming a single-input single-output system,

$$e = \underbrace{S(1 - GF)}_{\text{feedforward}} r - \underbrace{S}_{\text{feedback}} v - \underbrace{S}_{\text{feedback}} \eta \quad (2)$$

where v are disturbances affecting the system, and η is measurement noise. Also,

$$S = \frac{1}{1 + GK} \quad (3)$$

and

$$T = \frac{GK}{1 + GK} \quad (4)$$

are the sensitivity function and complementary sensitivity function, respectively. Essentially, three design variables have to be selected by the control engineer:

1. The reference signal r
2. The feedback controller K
3. The feedforward controller F

The reference often involves a point-to-point motion, where the goal is to reach an endpoint with high accuracy and minimal time. In particular, the reference is specified such that the actuator constraints are not violated, see Lambrechts et al (2005). In subsequent sections, feedback control and feedforward control are investigated.

frequency response function is depicted, confirming the model characteristics (note the inaccuracies at low and high frequencies due to a poor signal to noise ratio) (solid blue).

Control for Precision Mechatronics, Fig. 3 Motion control architecture.

Feedback Design for Performance

In this section, a motion control design procedure is outlined, leading to the feedback controller K in Fig. 3.

Accurate Models for Motion Feedback Control: Nonparametric System Identification

Any control design approach requires knowledge of the true system G , often in the form of a mathematical model. On the one hand, these models can be obtained through first-principles modeling, which typically leads to a model of the form (1) directly. This approach is often time consuming for mechanical systems and often leads to inaccurate parameters, e.g., the natural frequencies ω_i in (1). On the other hand, system identification or experimental modeling can be used, directly employing measured data. For mechanical systems, system identification is fast, accurate, and inexpensive, due to high signal-to-noise ratios and high sampling rates.

In system identification, roughly two approaches can be distinguished: nonparametric approach and parametric approaches. Nonparametric approaches, more specifically frequency response functions $G(\omega)$, have a key role in motion control for several reasons. An example of such a frequency response function is given in Fig. 2. First, these are used as a basis for loop-shaping design in the next section. Second, these are used as a basis for parametric identification, where these contribute to model order selection, i.e., the number of flexible modes n_s can be estimated from a Bode magnitude plot of $G(\omega)$, and model validation.

Frequency response identification of motion systems consists of the following steps.

1. Implement a stabilizing controller K
2. Apply a suitable excitation signal f and/or r in Fig. 3 and measure closed-loop signals y and u
3. Estimate $G(\omega)$ based on the measured data

An excellent treatment of these steps is given in Pintelon and Schoukens (2012, Chapter 2).

Major recent advancements include the use of periodic excitations instead of noise excitation and approaches to reduce transients, substantially increasing accuracy and reducing measurement time, see Voorhoeve et al (2018) for details on these recent advances and experimental results on motion systems.

Loop-Shaping Design

The goal of feedback in motion control is to minimize the error in (2) through selecting K in view of

1. Attenuating disturbances v through minimizing $|S|$.
2. Compensating for feedforward controller inaccuracies, i.e., the term $(1 - GF)r$ in (2) through minimizing $|S|$.
3. Reducing the effect of measurement noise η through minimizing $|T|$ since the transfer function from η to y is given by $-T$.
4. Guaranteeing closed-loop stability, i.e., stability of the closed-loop transfer functions S , T , etc.

These goals are conflicting due to performance constraints, including the easily verifiable relation $S + T = 1$, in addition to the Bode sensitivity integral that reveals that S cannot be small at all frequencies, e.g., Åström and Murray (2008, Sect. 11.5). For motion systems, Requirement 2 is mainly important at low frequencies, whereas Requirement 3 is mainly important at high frequencies where the measurement noise η is relatively large compared to the reference signal. Minimizing $|T|$ implies $|S| = 1$, which essentially implies the controller does not react on measurement noise in the measured error (2).

The idea in loop-shaping is to select K that directly affects the loop-gain $L = GK$. Indeed, L can be directly manipulated by the choice of K using Bode and Nyquist diagrams, see, e.g., Åström and Murray (2008, Sect. 11.4). In turn, L directly connects to the closed-loop transfer functions in certain frequency ranges. Loop-shaping typically consists of the following steps, which are typically re-tuned in an iterative fashion.

1. Pick a crossover frequency f_{bw} [Hz], which is the frequency where $|L(2\pi f_{bw})| = 1$. Typically, $|S| < 1$ below f_{bw} , while $|T| < 1$ beyond f_{bw} . Furthermore, f_{bw} is typically selected in the region where the rigid-body modes dominate, i.e., $f_{bw} < \frac{\omega_i}{2\pi}$, where $\omega_i, i = n_{rb} + 1, \dots, n_s$ is defined in (1).
2. Implement a lead filter, typically specified as $K_{lead} = p_{lead} \frac{\frac{1}{2\pi \cdot \frac{1}{3} f_{bw}} + 1}{\frac{1}{2\pi \cdot 3 f_{bw}} + 1}$, such that sufficient phase lead is generated around f_{bw} . In particular, the zero is placed at $\frac{1}{3} f_{bw}$, while the pole is placed at $3 f_{bw}$. Next, p_{lead} is adjusted such that $|GK_{lead}(2\pi f_{bw})| = 1$. This lead filter generates a phase margin at f_{bw} . Indeed, the phase corresponding to the rigid-body dynamics in (1) is typically -180° , see Fig. 2, which leads to a phase margin of 0° .
3. Check stability using Nyquist plot of GK and include possible notch filters in the case where the flexible modes endanger robust stability.
4. Include integral action through $K = K_{int} K_{lead}$, with $K_{int} = \frac{s + 2\pi \frac{f_{bw}}{5}}{s}$. Since $GK \gg 0$ at low frequencies, $S \approx \frac{1}{GK}$, the integrator pole at $s = 0$ improves low frequency disturbance attenuation while not affecting phase margin due to the zero at $\frac{1}{5} f_{bw}$.

These steps are done iteratively based on Nyquist of GK and Bode plots of GK and closed-loop transfer functions. Most importantly, all these steps can be performed on the basis of frequency response functions. This is essential, since nonparametric frequency response function identification leads to fast and inexpensive models, while at the same time delivering much more accurate models for feedback control. This latter accuracy aspect is directly confirmed by Fig. 2, where the frequency response function takes into account additional artifacts such as delay in the entire actuation chain, which is essential for stability, i.e., it directly affects the phase margin. To show this, the controller design procedure is directly applied to the frequency response function of the system G , see Fig. 4. An interesting observation is that the frequency response function is typically accurate in the

crossover region, i.e., where $|L(2\pi f_{bw})| \approx 1$, which is the most important region for closed-loop stability. In sharp contrast, the frequency response function is very noisy at low frequencies and high frequencies, but these regions much less relevant for closed-loop control (Oomen 2018).

Multivariable Motion Control: A Systematic Design Framework

Most motion systems are multivariable, and commonly positioning is required in all six motion degrees of freedom. Since the design approach in the previous section focuses on single-input single-output systems, approaches developed particularly for multivariable systems, including those based on $\mathcal{H}_2$ or $\mathcal{H}_\infty$ optimization, may become appealing. However, these approaches require parametric models, and these models are user-intensive and time consuming to obtain. Therefore, a systematic motion feedback control design procedure based on frequency response functions has been developed that extends the loop-shaping procedure in the preceding approach toward multivariable systems. This procedure consists of the following steps.

Procedure 1 Advanced motion control design procedure.

1. Interaction analysis. Is the system decoupled?
 - Yes: independent SISO design. No: next step
 2. Static decoupling. Is the system decoupled?
 - Yes: independent SISO design. No: next step
 3. Decentralized MIMO design: loop-closing procedures
 - Robustness for interaction, e.g., using factorized Nyquist design
 - Design for interaction, e.g., sequential loop closing design
 Not successful? Next step
 4. Optimal & robust control
 - Design of centralized controller using a parametric model and optimization algorithms
-

Details on the procedure are provided in, e.g., Oomen (2018, Section 4), where many technical steps from Skogestad and Postlethwaite (2005) are employed. The main point is that the overall design complexity gradually increases.

Control for Precision Mechatronics, Fig. 4 Feedback controller tuning. Identified system G frequency response function (solid blue), loop-gain GK_{lead} with lead con-

troller (dashed red), lead controller K_{lead} (dash-dotted green), gain margin (magenta square), phase margin (cyan diamond)

Therefore, the complexity is only increased if necessitated by the control requirements. In particular, Step 1 – Step 3 are based on inexpensive frequency response functions and essentially involve an increased complexity in controller tuning. Step 4 involves a major increase in complexity from two perspectives: it requires an accurate parametric model in view of the control objectives and it requires the specification of all performance and robustness objectives in a single scalar criterion.

Feedforward

Feedforward Control Structure

Essentially, the main goal of the feedback controller in the preceding section is to deal with uncertainty, both in terms of disturbances, e.g., v in (2), and in terms of system dynamics, e.g., residual $(1 - GF)r$ due to incomplete knowledge of G in the design of feedforward control. In sharp contrast, the goal of feedforward control is

to obtain an accurate feedforward F that compensates for the known reference signal r .

The design of the feedforward controller is based on the physical model (1), and a systematic manual tuning approach is developed by exploiting (2). To exemplify the approach, note that the model (1) for single-input single output systems at low frequencies approximately corresponds to rigid-body behavior:

$$\frac{1}{ms^2}, \quad (5)$$

where $m \in \mathbb{R}_+$ corresponds to the mass of the system. Therefore, a candidate feedforward controller F is $F = k_{fa}s^2$, which leads to the feedforward signal $f(s) = k_{fa}s^2r(s)$ corresponding to $f(t) = k_{fa}\frac{d^2r(t)}{dt^2}$. This feedforward therefore is also referred to as acceleration feedforward, being the second derivative of the reference signal $r(t)$. Then, the first term in (2) becomes

$$e = S(1 - GF)r = S\left(1 - \frac{k_{fa}}{m}\right)r \quad (6)$$

Manual Tuning Approach

In (6), a feedforward structure has been selected, which clearly minimizes the error if $k_{fa} = m$. However, accurate knowledge of m is typically not available. The main idea is to directly use experimental data to estimate the optimal value of k_{fa} . To this end, assume that a stabilizing feedback controller is implemented as in the preceding section, typically of the form K_{lead} , yet without implementing the integral action K_{int} . This implies that at low frequencies, where $|GK| \gg 1$,

$$S \approx \frac{1}{GK} \approx cs^2 \quad \text{for frequencies} \\ \text{where } |GK| \gg 1, \quad (7)$$

with c a constant. Combining this with (6) leads to

$$e = cs^2 \left(1 - \frac{k_{fa}}{m}\right) r, \quad (8)$$

and after taking an inverse Laplace transform, this becomes

$$e(t) = c \left(1 - \frac{k_{fa}}{m}\right) \frac{d^2 r(t)}{dt^2}. \quad (9)$$

Equation (9) now directly reveals how to tune the coefficient k_{fa} : select it such that the measured error $e(t)$ is not correlated with the acceleration signal $\frac{d^2 r(t)}{dt^2}$. This is done by performing an experiment under normal operating conditions, i.e., a servo task with a certain reference r implemented. Typically, the experimental length for motion systems is in the order of seconds; hence, this procedure can be performed in a short amount of time. This allows to directly tune k_{fa} , typically through a manual adaptation. This is straightforward, since from (9) the error depends affinely on k_{fa} .

This idea of tuning naturally extends to more feedforward components, and a typical feedforward controller consists of

$$f(t) = k_{fc} \text{sign} \left(\frac{dr(t)}{dt} \right) + k_{fv} \frac{dr(t)}{dt} \\ + k_{fa} \frac{d^2 r(t)}{dt^2} + k_{fs} \frac{d^4 r(t)}{dt^4}, \quad (10)$$

where k_{fc} and k_{fv} compensate for Coulomb and viscous friction, and k_{fs} is a snap feedforward, aiming to compensate for the compliance of the flexible dynamics in (1). Indeed, at low frequencies, (1) becomes

$$\frac{1}{ms^2} + D, \quad (11)$$

where $D \in \mathbb{R}$ is a static term that corresponds to the low frequency behavior of the flexible modes in (1), i.e., below the resonance frequencies ω_i , $i = n_{rb} + 1, \dots, n_s$. Next, since the essential mechanism is to select the feedforward controller F as the inverse of the model, inverting (11) leads to

$$\left(\frac{1}{ms^2} + D \right)^{-1} = \frac{ms^2}{1 + ms^2 D} \\ = ms^2 - \frac{m^2 s^4 D}{1 + ms^2 D}. \quad (12)$$

Again considering this inversion at low frequencies implies that the limit $s \downarrow 0$ leads to the approximation

$$ms^2 - m^2 D s^4, \quad (13)$$

thereby extending the earlier acceleration feedforward toward a fourth derivative, which is referred to as snap feedforward. Practically, this snap feedforward compensates for the compliance in mechanical systems.

The tuning of these coefficients involves the selection of an appropriate reference, typically consisting of equal parts of acceleration, constant velocity, and deceleration. Then, these are tuned systematically in the typical order: k_{fc} , k_{fv} , k_{fa} , k_{fs} .

In Fig. 5, this procedure is applied to the printer system in Fig. 1. Here, the parameters k_{fc} and k_{fv} are already set to their optimal value. Next, the value of k_{fa} is varied. It can clearly be observed that an incorrect value leads to a strong correlation between the reference and the measured error profile, see (9). The value of k_{fa} is then varied until there is no correlation between the acceleration profile.

Control for Precision Mechatronics, Fig. 5 Feed-forward controller tuning. Error using feedback only (solid blue). Next, friction feedforward has been optimally tuned, and acceleration feedforward tuning is further investigated. Indeed, note that the error profile (dash-dotted green) has a strong correlation with the acceleration

profile. Increasing the parameter value leads to a reducing error, from dash-dotted green toward dotted magenta which is considered the optimal tuning. Also shown are the scaled acceleration profile (black dashed) and scaled reference profile r (black dash-dotted).

Automated Tuning and Learning

In the preceding section, a systematic approach to manually tune feedforward signals has been outlined. Recently, this approach has also been extended toward automated tuning of feedforward controllers from data. Two important classes can be distinguished:

1. Approaches that learn a signal f in Fig. 3 directly, including iterative learning control Bristow et al (2006)
2. Approaches that learn the parameters in a parameterized form such as (10), including iterative learning control with basis functions and instrumental variable identification based, see Blanken et al (2017) for an overview as well as experimental results for tuning multiple parameters as in (10)

While the former approaches have a larger optimization space, and can therefore potentially

achieve a smaller error e , these approaches lead to a high sensitivity for setpoint changes r . Indeed, the second class of approaches is invariant under a change of setpoint, which is a very common requirement in motion control applications, where a class of references trajectories is common.

Summary and Future Directions

Control in precision mechatronics involves a deep understanding of the physical system properties, control theory, and design engineering aspects, which is reflected by the systematic design procedure outlined in this entry. This procedure forms the basis for successful motion control.

In the near envisaged future, an immense increase in system complexity is foreseen, where it is expected that more steps are required in Procedure 1. Indeed, system complexity will dras-

tically increase due to the following envisaged developments, see Oomen (2018) for details.

- Motion control will become a multiphysics problem. For instance, increasing accuracy requirements in the sub-nanometer range lead to a situation where thermal aspects become increasingly important. These thermal aspects lead to deformations, which will lead to an interaction with motion control. Already active thermal control and setpoint adjustment for thermal deformations are being developed.
- Subsystems will interact. In high-tech systems, multiple motion systems cooperatively perform tasks. For instance, in modern wafer scanners for lithographic integrated circuit production, two precision systems have to position relative to each other, directly leading to coupling.
- Many actuators and sensors will be used. In particular, the flexible dynamics in (1) limit the achievable crossover frequency f_{bw} . By using additional inputs and outputs, these flexible dynamics can be actively controlled. However, this leads to an increased complexity of the control design problem.
- Deformations lead to a situation where performance variables are not directly measurable. In particular, the flexible dynamics in (1) lead to a situation where flexible dynamics lead to deformation in between different locations on the mechanical structure. Since the sensors can typically not be placed exactly at the desired location, e.g., due to the presence of a product, this implies that performance cannot be measured directly. This leads to an inferential motion control problem, essentially introducing another set of unmeasurable performance signals into the control problem.

From a feedforward perspective, the mechatronic system design with embedded controller implementations leads to the availability of large amounts of sensor data. This facilitates the learning from data in complex motion systems. These algorithms, which have to be applicable to massively multivariable systems, are foreseen to revitalize existing machines through inexpensive,

smart updates, that lead to continuous control performance improvement during normal operation through optimizing f in Fig. 3.

Summarizing, positioning systems have a key role in engineered systems, and their role is foreseen to further increase in the near future. Smart control solutions will enable a further increase toward unparalleled accuracy and speed and create opportunities for revolutionary machine designs. This will enable manufacturing of user-customizable and unimaginable products and scientific instruments that facilitate scientific discoveries in nanotechnology, biotechnology, and space exploration.

Control Hierarchy of Large Processing Plants: An Overview

César de Prada

Departamento de Ingeniería de Sistemas y Automática, University of Valladolid, Valladolid, Spain

Abstract

This entry provides an overview of the so-called automation pyramid, which organizes the different types of control and operation tasks in a processing plant in a set of interconnected layers, from basic control and instrumentation to plant-wide economic optimization. These layers have different functions, all of them necessary for the optimal functioning of large processing plants.

Keywords

Control hierarchy · Automation pyramid · Plant-wide control · MPC · RTO · Optimization

Introduction

Operating a process plant is a complex task involving many different aspects ranging from the control of individual pieces of equipment or process units to the management of the plant or factory as a whole, including interactions with other plants or suppliers.

From a control point of view, the corresponding tasks are traditionally organized in several layers, with the ones closer to the physical processes placed in the bottom and those closer to plant-wide management in the top, forming the so-called automation pyramid represented in Fig. 1.

The process industry currently faces many challenges, originating from factors such as increased competition among companies, better global market information, new environmental regulations and safety standards, improved quality, or energy efficiency requirements. Many years ago, the main tasks in the operation of a process plant were associated with the correct and safe functioning of the individual process units and to the global management of the factory from the point of view of organization and economy. Therefore, only the lower and top layers of the automation pyramid were realized by computer-based systems, whereas the intermediate tasks were largely performed by human operators and managers. Nevertheless, more and more, the automation of the intermediate layers and the integration among all decision levels are gaining importance in order to face the above mentioned challenges.

Above the physical plant represented in the bottom of Fig. 1, there is a layer related to instrumentation and basic control, devoted to obtaining direct process information and stabilizing the plant and maintaining selected process variables close to their desired targets by means of local controllers. Motivated by the need for more efficient operation and better-quality assurance, an improvement of this basic control can be obtained using control structures such as cascades, feed forwards, ratios, and selectors. Sometimes, this is called advanced control in industry, but not in

Control Hierarchy of Large Processing Plants: An Overview, Fig. 1 The automation pyramid

C

academia, where the term is reserved for more sophisticated controls.

A big step forward took place in the control field with the introduction of model-based predictive control (MPC) in the late 1970s and 1980s (Industrial MPC of Continuous Processes; Camacho and Bordóns 2004). MPC aims at commanding a process unit as a whole considering simultaneously all its manipulated and controlled variables. It uses a process model in order to compute the control actions that optimize a control performance index considering all interactions among its variables, disturbances, and process constraints. MPC is built on top of the basic control loops and partly replaces the complex control structures of the advanced control layer adding new functionalities and better control performance.

The improvements in control quality and the management of constraints and interactions of the model-predictive controllers open the door for the implementation of local economic optimization in an upper layer. Linked to the MPC

Control Hierarchy of Large Processing Plants: An Overview, Fig. 2

MPC implementation with a local optimizer

controller, and taking advantage of its model, an optimizer may look for the best operating point of the unit by computing the controller set points that optimize an economic cost function of the process considering the operational constraints of the unit. This task is usually formulated and solved as a linear programming (LP) problem, i.e., based on linear or linearized economic models and cost function (see Fig. 2).

A natural extension of these ideas was to consider the interrelations among the different parts of a processing plant and to look for the steady-state operating point that provides the best economic return and minimum energy expense or optimizes any other economic criterion

while satisfying the global production aims and constraints. These optimization tasks are known as real-time optimization (RTO) (Real-Time Optimization of Industrial Processes) and form another layer of the automation pyramid. In batch plants, this layer involves production scheduling, focused in determining when and where tasks should be performed in order to maximize a certain cost function while respecting operation constraints.

Finally, when we consider the operation of the whole plant, obvious links between the RTO and the planning and economic management of the company appear. In particular, the organization and optimization of the flows of raw materials, purchases, etc., involved in the supply chains, present important challenges that are placed in the top layer of Fig. 1.

This entry provides an overview of the different layers and associated tasks so that the

reader can place in context the different types of controllers and related functionalities and tools. It also aims at summarizing current trends in process control and process operation, focusing the attention toward the higher levels of the hierarchy and the optimal operation of large-scale processes.

Industrial Implementation

The implementation of the tasks and layers previously mentioned in a process factory is possible nowadays due to important advances in many fields, such as modeling and identification, control and estimation, optimization methods, and, in particular, software tools, communications, and computing power. Today, it is rather common to find in many process plants an information network that follows also a pyramidal structure represented in Fig. 3.

Control Hierarchy of Large Processing Plants: An Overview, Fig. 3 Information network in a modern process plant

At the bottom, there is the instrumentation layer that includes not only sensors and actuators connected by the classical analog 4–20 mA signals (possibly enhanced by the transmission of information to and from the sensors using the HART protocol) but also digital field buses and wireless networks connected to smart transmitters and actuators that deliver improved information and intelligence. New functionalities, such as remote calibration, filtering, self-test, and disturbance compensation, provide more accurate measurements that contribute to improving the functioning of local controllers, in the same way as the new methods and tools available nowadays for instrument monitoring and fault detection and diagnosis. The increased installation of wireless transmitters and the advances in analytical instrumentation will lead in the near future, without doubt, to the development of a stronger information base to support better decisions and operations in the plants.

Information from transmitters is collected in control rooms that perform the control tasks. Many of them are equipped with distributed control systems (DCS) that implement monitoring and control tasks. Field signals are received in the control cabinets where a large number of microprocessors execute the data acquisition and regulatory control tasks, sending signals back to the field actuators. Internal buses connect the controllers with the computers that support the displays of the human-machine interface (HMI) for the plant operators of the control room. In the past, DCS were mostly in charge of the regulatory control tasks, including basic control, alarm management, and historians, while interlocking systems related to safety and sequences related to batch operations were implemented in programmable logic controllers (PLCs): Programmable Logic Controllers. Today, the differences between both types of systems are not so clear, due to the increase in computing power of the PLCs and the added functionalities of the DCS. Safety instrumented systems (SIS) for the maintenance of plant safety are usually implemented in dedicated PLCs, if not hardwired, but for the rest of the functions, a combination of PLC-like processors with I/O cards and SCADAs

(Supervision, Control, and Data Acquisition Systems) is the prevailing architecture. SCADAs act as HMI and information systems collecting large amounts of data that can be used at other levels with different purposes. At the same time, as these systems are based on standard operating system (e.g., Windows), they are more vulnerable to external software attacks, which has brought the topic of cybersecurity of the control systems to the front line of the concerns affecting safety and security of process plants.

Above the control layer, using the information stored in the SCADA as well as other sources, there is an increased number of applications covering diverse fields. Figure 3 depicts the perspective of the computing and information flow architecture and includes a level called supervisory control, placed in direct connection with the control room and the production tasks. It includes, for instance, MPC with local optimizers, statistical process control (SPC) for quality and production supervision (Multiscale Multivariate Statistical Process Control), data reconciliation, inferences and estimation of unmeasured quantities, fault detection and diagnosis, or performance controller monitoring (Controller Performance Monitoring) (CPM).

The information flow becomes more complex when we move up the basic control layer, looking more like a web than a pyramid when we enter the world of what can be called generally as asset (plant and equipment) management: a collection of different activities oriented to sustain performance and economic return, considering their entire cycle of life and, in particular, aspects such as maintenance, efficiency, or production organization. Above the supervisory layer, one can usually distinguish at least two levels denoted generically as manufacturing execution systems (MES) and enterprise resource planning (ERP) (Scholten 2009) as can be seen in Fig. 4.

MES are information systems that support the functions that a production department must perform in order to prepare and to manage work instructions, schedule production activities, monitor the correct execution of the production process, gather and analyze information about the production process, and optimize procedures.

Control Hierarchy of Large Processing Plants: An Overview,
Fig. 4 Software/hardware view

Notice that regarding the control of process units, up to this level, no fundamental differences appear between continuous and batch processes. But at the MES level, in which RTO of Fig. 1 is inserted, many process units may be involved, and the tools and problems are different, the main task in batch production being the optimal scheduling of those process units (Scheduling of Batch Plants; Mendez et al. 2006).

MES are part of a larger class of systems called manufacturing operation management (MOM) that cover not only the management of production operations but also other functions such as maintenance, quality, laboratory information systems, or warehouse management. One of their main tasks is to generate elaborate information, quite often in the form of key performance indicators (KPIs), with the purpose of facilitating the implementation of corrective actions.

Finally, ERP systems represent the top of the pyramid, corresponding to the enterprise business planning activities that allow assigning global targets to production scheduling. For many years, it has been considered to be out of the scope of the field of control, but nowadays, more and more, supply chain management is viewed and addressed as a control and optimization problem in research.

Future Control and Optimization at Plant Scale

Going back to Fig. 1, the variety of control and optimization problems increases as we move up in the control hierarchy, entering the field

of dynamic process operations which considers not only individual process units but also larger sets of equipment or whole plants. Examples of challenges at the RTO (or MES) level are optimal management of shared resources or utilities deciding on their best use or distribution, production bottleneck avoidance, optimal energy use or maximum efficiency, smooth transitions against production changes, optimal process operation taking into account its long-term effects on efficiency degradation (fouling, catalyst degradation, etc.) and maintenance, etc.

Above, we have mentioned RTO as the most common approach for plant-wide optimization. Normally, RTO systems perform the optimization of an economic cost function using a nonlinear process model in steady state and the corresponding operational constraints to generate targets for the control systems on the lower layers. The implementation of RTO provides consistent benefits by looking at the optimal operation problem from a plant-wide perspective. Nevertheless, in practice, when MPCs with local optimizers are operating the process units, many coordination problems appear between these layers, due to differences in models and targets, so that driving the operation of these process units in a coherent way with the global economic targets is an additional challenge.

A different implementation perspective is taken by the so-called self-optimizing control (Fig. 5 right, Skogestad 2000) that, instead of implementing the RTO solution online, uses it to design a control structure that assures a near-optimum operation if some specially chosen variables are maintained closed to their targets.

Control Hierarchy of Large Processing Plants: An Overview, Fig. 5 Two possible implementations of RTO

As with any model-based approach, the important problem of how to implement or modify the theoretical optimum computed by RTO so that the optimum computed with the model and the real optimum of the process coincide in spite of model errors, disturbances, etc., emerges. A common choice to deal with this problem is to update periodically the model using parameter estimation methods or data reconciliation with plant data in steady state, but this is known not to solve the problem if there are structural errors in the model. Also, uncertainty can be explicitly taken into account by considering different scenarios and optimizing the worst case, but this is conservative and does not take advantage of the plant measurements. Along this line, there are proposals of other solutions such as modifier-adaptation methods that use a fixed model and process measurements to modify the optimization problem so that the final result corresponds to the process optimum (Marchetti et al. 2009) or the use of stochastic optimization where several scenarios are taken into account and future decisions are used as recourse variables (Lucia et al. 2013).

RTO is formulated in steady state but, in practice, most of the time the plants are in transients, and there are many problems, such as start-up or batch optimization, that require a dynamic formulation. A natural evolution in this direction is to integrate nonlinear MPC with economic optimization so that the target of the NMPC

is not set point following but direct economic optimization as in the right-hand side of Fig. 6: Economic Model-Predictive Control and Model-Based Performance Optimizing Control (Engell 2007).

The type of problems that can be formulated within this framework is very wide, as well as the possible fields of application. Processes with distributed parameter structure or mixtures of real and on/off variables, batch and continuous units, statistical distribution of particle sizes or properties, etc., give rise to special type of NMPC problems (see, e.g., Lunze and Lamnabhi-Lagarrigue 2009), but a common characteristic of all of them is the fact that they are computational intensive and should be solved taking into account the different forms of uncertainty always present.

Control and optimization are nowadays inseparable essential parts of any advanced approach to dynamic process operation. Progress in the field and spreading of the industrial applications are possible, thanks to the advances in optimization methods and tools and computing power available on the plant level, but implementation is still a challenge from many points of view, not only technical. Developing efficient process models for advanced control and optimization is perhaps the most difficult point, but, in addition, few suppliers offer commercial products at this level, and finding optimal operation policies for a whole factory is a complex task that requires taking into consideration many aspects, cooperation among departments and elaborate information not available directly as process measurements. Regarding

Control Hierarchy of Large Processing Plants: An Overview, Fig. 6 Direct dynamic optimization

this point, data analysis techniques may help in obtaining that information complementing well-established modeling methodologies.

Another difficulty about implementation of advanced solutions resides in the fact that most current commercial products do not facilitate the integration of new methods or best-in-class, third-party components into fundamentally closed, proprietary systems, in spite of the facilities provided by tools like *OPC*. Moreover, today's systems generally lack the built-in cybersecurity needed to protect operations or equipment assets.

This has originated proposals for changing the hierarchical architecture of Fig. 1, where the information flows vertically inside quite closed boundaries, by other ones oriented to facilitate the integration of external hardware/software into the control systems. One example is the NAMUR Open Architecture (*NOA*), which claims for a second open communication channel at each automation pyramid level for additional functionalities that are not part of the core control components. In the same line, the architecture proposed by the Open Process Automation Forum (*OPAF*) within the Open Group replaces the automation pyramid by a flat structure where each production oriented IT-system can communicate directly with each other IT-system in a secure, reliable and timely manner. The collection of standards defined as O-PAS (Open Process Automation Standards) define specifications for an open, interoperable, secure by design automation architecture. The standards enable the development of systems composed of cohesive, loosely coupled, functional elements acquired from different suppliers and easily integrated via a structured modular architecture.

Within the new elements that likely we will see included in the systems supported by these new architectures are digital twins of the plants. They will combine detailed simulation of the processes with updated real-time information of the process and databases of different functional elements, helping in the decision-making by providing integrated information and online what-if analysis.

Control Hierarchy of Large Processing Plants: An Overview, Fig. 7 Hierarchical, price coordination, and distributed approaches

Another point related to architectures is the fact that implementation of large advanced control or optimization solutions in real time may require breaking the associated optimization problem in more manageable subproblems that can be solved in parallel. This leads to several local controllers/optimizers, each one solving one subproblem involving variables of a part of the process and linked by some type of coordination. These solutions offer a new point of view of the control hierarchy. Typically, three types of architectures are mentioned for dealing with the problem, represented in Fig. 7: In the hierarchical approach, coordination between local controllers is made by an upper layer that deals with the interactions, assigning targets to them. In price coordination, the coordination task is performed by a market-like mechanism that assigns different prices to the cost functions of every local controller/optimizer as a way of coordinating their actions. Finally, in the distributed approach,

the local controllers coordinate their actions by interchanging information about its decisions or states with neighbors (Scattolini 2009).

Regarding topics considered in the different problems that have been mentioned, perhaps there are two types of them that draw some of the trends that can be observed in process operation optimization. One considers the long-term effects of current decisions on the useful life and future state of the processes. Here, we refer to phenomena such as heat-exchanger fouling or catalyst degradation in chemical reactors that are affected by the way one operates a process. Notice that modes of operation that may be optimum considering only cost and benefits at present may not be so optimum in the long term due to the additional cost of more frequent maintenance that may imply. Models of degradation and more sophisticated mathematical formulations covering large time scales are required to deal with them, but there is no doubt that they represent a more realistic view of what is needed in the industrial practice.

The second trend is associated with the integration of decisions at different levels of the automation pyramid, in particular between production scheduling with upper- and lower-level decisions, ranging from logistics and supply chains to MPC and RTO. This points at generating optimal production schedules able to make an efficient use of the resources and adapt themselves to the changing environmental conditions, internal or external, such as varying electricity prices, products demand, transport delays, or maintenance works. The problems of this type are formulated normally as large-scale Mix Integer Programming ones, involving many real and binary variables and, on addition to computing power, efficient model formulation and perhaps decomposition techniques for its solution, claim for more integrated flows of information in the factories and new open control architectures for implementation like the ones mentioned above (NAMUR, OPAF).

Summary and Future Research

Process control is a key element in the operation of process plants. At the lowest layer, it can

be considered a mature, well-proven technology, even if there are still open problems such as control structure selection or automatic controller tuning. But the range of open problems increases in the upper layers of the hierarchy: from modelling and estimation to efficient large-scale optimization, robustness against uncertainty and the integration of the decisions at the different levels. This leads to new defies and research problems which solution will bring large improvements in the efficiency and operability of process plants. Different methods and architectures are being proposed to meet the challenges. Their implementation at industrial scale requires efforts and people with multidisciplinary background, but they will pave the road to the future leading to fully automated and efficient process factories.

Control of Additive Manufacturing

Sandipan Mishra

Department of Mechanical, Aerospace, and Nuclear Engineering, Rensselaer Polytechnic Institute, Troy, NY, USA

Abstract

Control of additive manufacturing (AM) processes involves delivery of material and energy to precise locations at prescribed times during the manufacturing process. While each process is distinct and thus the challenges associated with designing control algorithms are unique, *motion control* and *process control* are the two primary objectives in all AM processes. Standard motion control strategies are used to position nozzles, motion stages, and steering mirrors. Model-free feedback and feedforward design strategies such as PID and iterative learning control are often used for process control of low-level process variables. On the other hand, geometry and

part-level control strategies are designed through physics-based in-layer and layer-to-layer models built on momentum, mass, and/or energy balance equations.

Keywords

3D printing · Motion control · Process control · Model predictive control · Physics-based modeling · Gray-box modeling · Iterative learning control · 2D systems · Feedback linearization

Introduction

Additive manufacturing (AM), also called 3D printing, refers to a class of manufacturing processes where material is added layer upon layer to construct 3D objects. Recently, AM has seen significant increase in popularity for commercial as well as R&D applications. AM processes encompass several technologies that use different materials to build parts, including polymers, plastics, ceramics, and metals. As defined by ASTM Standard F2792-12a (ASTM International 2012), AM is “a process of joining materials to make objects from three-dimensional (3D) model data, usually layer upon layer.” Broadly speaking, AM processes may be classified into the following categories: (1) binder and material jetting, (2) directed energy deposition, (3) material extrusion, (4) powder bed fusion, (5) sheet lamination, and (6) vat polymerization. This classification is based on the type of material, the type of energy source, and/or the mechanism for energy and material delivery used in the AM process. Thus, *from a control standpoint, AM processes fundamentally require delivering a specified amount of material and energy at prescribed locations and time.* Naturally, the specific modality of the process dictates the mechanisms by which material and energy are delivered, and consequently the sensing, modeling, and control methodologies developed are significantly distinct for each process. The following sections briefly describe AM modeling and control paradigms for three candidate processes.

Binder and Material Jetting: Inkjet 3D Printing

Material and binder jetting AM processes consist of a moving nozzle depositing ink droplets either of the build material itself or a binder ink onto a bed of build material (In some configurations, the nozzle is held stationary while the substrate is moved by motion stages.), followed by a material curing step. One example of such a process is inkjet 3D printing, where 3D objects are manufactured by jetting polymeric inks layer upon layer with ultraviolet (UV) light or heat curing steps in between. The droplets are ejected from the nozzle through either (1) piezoelectric actuation, (2) thermal actuation, or (3) ultrasonic actuation. In commercial systems, the stage motion is executed by an industrial motion stage controller (with position or angle feedback), which may send triggers to the nozzle to eject droplets. The droplet generation process is open-loop, i.e., the number of layers to be deposited and the droplet patterns for each layer are determined in advance. Furthermore, the voltage profiles for ejecting droplets from the nozzle are determined through trial-and-error and pre-programmed for each print job.

Control of Droplet Ejection

For the traditional 2D ink-jet printing process, ink channel dynamics models that describe the relationship between the input voltage waveform and droplet characteristics (sensed through the piezo sensor itself and/or camera measurements

of the droplet ejection) have been studied extensively to design the waveforms for high speed and reliable droplet deposition (Kwon and Kim 2007). These models relate the input waveform to droplet volume and jetting frequency. The input waveform is optimized empirically to generate consistent prescribed droplet volumes and jetting frequency. Iterative learning control (ILC) has also been used for waveform optimization for inkjet nozzles (Wassink et al. 2005).

Geometry Control in Inkjet 3D Printing

Given a consistent and reliable droplet generation mechanism, the natural next step for process control in inkjet 3D printing is *geometry-level* control (Doumanidis and Skordeli 2000; Cohen and Lipson 2010; Lu et al. 2015). Geometry control strategies determine droplet patterns (and volume deposited at each location) based on in situ geometry measurements of the part being built.

Figure 1 illustrates the schematic of closed-loop control of geometry in inkjet 3D printing. The desired part geometry is denoted by $h_d \in \mathbb{R}^n$, and the current layer height profile is denoted by $h_L \in \mathbb{R}^n$, where L indicates the layer number and n is the number of grid points. h_L , h_d , and u_L represented the vectorized versions of the 2D height and input maps H_L , H_d , and U_L , respectively. The input sequence (droplet pattern) $u_L \in [V_{\min}, V_{\max}]^n$ and the current height h_L together determine the height profile for the subsequent layer, h_{L+1} . Droplet volumes at each location are limited by nozzle and ink properties, with bounds

Control of Additive Manufacturing, Fig. 1 A schematic block diagram of the closed-loop layer-to-layer printing process

given by $V_{\min}$ and $V_{\max}$. The control objective is to generate a droplet pattern u_{L+1} that minimizes the geometric tracking error $e_{L+1} = h_d - h_{L+1}$, based on feedback of the height profile, h_L . The control algorithm is designed based on layer-to-layer height evolution models of the printing process, which can be either physics-based, identified from input-output data (black box), or obtained from a combination of the two (gray-box).

Layer-to-Layer Models A generic *time-step wise* height evolution model is given by $h_{k+1} = f(h_k, u_k)$ where k denotes the time-step within a layer and u_k is the droplet volume at a given time-step. The layer-to-layer height evolution model is then obtained by lifting this equation N time-steps, where N is the number of time-steps in a single layer. Abusing notation, the layer-to-layer model can be written in the form $h_{L+1} = F(h_L, U_L)$, where U_L is the droplet volume vector for an entire layer and L is the *layer number*.

The simplest model describing time-step geometry evolution is a linear additive height profile model: $h_{k+1} = h_k + B_k u_k$, where B_k captures the effect of a deposited droplet, which depends on the nozzle location (which depends on time k) and the droplet shape (which is independent of k). We refer the reader to Hoelzle and Barton (2016) for a detailed development of this model. The corresponding lifted LTI layer-to-layer model is

$$h_{L+1} = h_L + \mathcal{B}U_L, \quad (1)$$

where $\mathcal{B} \in \mathbb{R}^{n \times n_u}$, n_u being the number of droplet deposition locations in each layer. Adding flow effects to this model results in layer-to-layer dynamics of the form

$$h_{L+1} = \mathcal{A}h_L + \mathcal{B}U_L, \quad (2)$$

where $\mathcal{A} \in \mathbb{R}^{n \times n}$ depends on the adjacency of grid points and the flowability of the ink (Guo et al. 2018). This model is still discrete-time LTI and suitable for control design based on linear system theory.

Model-Based Control Design A variety of feedback control algorithms may be designed based on the model in Eq. (2). However, given the need for enforcing explicit constraints on droplet size and the availability of sufficient time in between layers for computation, model predictive control (MPC) schemes are particularly well-suited for this application. Thus, an MPC problem of the following form can be posed (Rawlings and Mayne 2012):

$$U^* = \arg \min_U J(h_L, U) \quad (3)$$

$$\text{s.t. } \mathcal{E}U^T \leq c,$$

where $U = [u_{0|L} \dots u_{N-1|L}]$, $u_{i|L}$ indicates the i th layer control input in the receding horizon. The cost function J penalizes tracking error:

$$J(h_L, U_L) = (h_{N_c|L} - h_{d,N_c|L})^T P (h_{N_c|L} - h_{d,N_c|L}) + \sum_{i=0}^{N_c-1} \left[(h_{i|L} - h_{d,i|L})^T Q (h_{i|L} - h_{d,i|L}) \right], \quad (4)$$

where $h_{i|L}$ indicates the predicted height profile i layers into the receding horizon, which is obtained by propagating the model (2) i layers starting with $h_{0|L} = h_L$. N_c is the prediction (and control) horizon. P and Q are positive-definite matrices, Q is the state penalty matrix, and P is the terminal penalty matrix that can be designed to guarantee MPC stability. In (3), $\mathcal{E}$ and c are matrix and column vectors defined by

$$\mathcal{E} = \begin{bmatrix} E_0 & \cdots & 0 \\ \vdots & \ddots & \vdots \\ 0 & \cdots & E_{N-1} \end{bmatrix} \quad c = \begin{bmatrix} b_0 \\ b_1 \\ \vdots \\ b_{N-1} \end{bmatrix}, \quad (5)$$

where $E_i = [-I \ I]^T$ and $b_i = [-u_{\text{low}} \ u_{\text{high}}]^T$ that defines the upper and lower constraints on the input droplet size. The optimization is performed each layer, and $u_{0|L}^*$ is applied. This MPC prob-

lem can be solved using centralized or distributed methods. We refer the reader to Guo et al. (2018) for a detailed development.

Powder Bed Fusion: Selective Laser Melting (SLM)

Selective laser melting (SLM) is a powder-bed fusion AM process that employs a high-power laser to melt and fuse metal layer by layer to build a 3D part. In the SLM process, a recoater spreads a thin layer of metal powder over the build plate. A laser scans this metal powder, which locally melts and then solidifies. A combination of a lens optics and a computer-controlled galvo scanner is used to control the spot size and drive the focused laser beam in a specified pattern, respectively (shown in yellow arrows in Fig. 2). The build plate is then lowered using a motion stage controller, and the recoater spreads a new layer of powder on top of the recently melted material, and the process is repeated for the next layer.

There are two controllable variables in the typical SLM process, the galvo scan path and the laser power profile. These are operated in a decoupled but coordinated manner: the galvo is driven by internal position control feedback to follow a prescribed path, while the laser power profile is controlled separately (usually in open loop). Typical measurements for feedback from

the process include infrared (IR) cameras (shown in blue) and photodiodes (or pyrometers). There are also safety mechanisms built in, such as an O₂ analyzer that is used to trigger alarms and stop the process in case of loss of seal of the chamber.

Feedforward Control Design For feedforward design, iterative learning control (ILC) can be used to find power profiles that maintain a constant melt pool geometry (y_d). Such ILC schemes are based on iterative refinement of the power profile $p(\cdot)$ based on error measurements $e(\cdot) = y_d - y(\cdot)$ obtained from prior iterations, based on an update law of the form

$$p_{j+1}(\cdot) = Q(p_j(\cdot) + Le_j(\cdot)) \quad (6)$$

where j represents the iteration number, L is the learning operator (often consisting of a gain and a forward shift), and Q is a low-pass filter for robustness. Repeating this update eventually yields the optimized power profile $p^*(\cdot)$

Model-Free Control Design The seminal experimental demonstration of *feedback* control of SLM to date is the PID controller presented in Craeghs et al. (2010). The control objective is to keep the melt pool size (area) constant. Two different feedback measurement mechanisms can be used to obtain a surrogate for the melt pool size: a high-speed CMOS camera and

Control of Additive Manufacturing, Fig. 2
Schematic of a typical SLM system and its components

a photodiode. The photodiode measurement is proportional to the melt pool area. The relationship between the input power $p(t)$ and the output melt pool area $y(t)$ can be approximated as a first-order transfer function $G(s) = \frac{K}{\tau s + 1}$, where K and τ are identified experimentally from step response measurements. The PID feedback control is

$$p(t) = p^*(t) + K_p e(t) + K_d \dot{e}(t) + K_i \int_0^t e(\tau) d\tau, \quad (7)$$

where $e(t) = y_d(t) - y(t)$ and $p^*(t)$ is the open loop feedforward power profile.

PDE Model-Based Control Design Reported literature on PDE model-based feedback control strategies for laser power control is limited. These approaches are based on modeling the SLM process approximately as a 1D advection-diffusion-reaction equation (a partial differential equation) of the form

$$U_t(x, t) = kU_{xx}(x, t) + v(t)U_x(x, t) - \alpha U(x, t) + p(t)\Pi(x). \quad (8)$$

where $p(\cdot)$ is the power profile, $v(\cdot)$ is the laser velocity, k and α are based on material properties, $\Pi(\cdot)$ is the laser spot shape, and U is the distributed temperature *field* (scaled and shifted by the ambient temperature T_∞). The laser power p and v can both be potentially used as control inputs. The subscripts t and x denote partial derivatives with respect to time and spatial coordinates, respectively. The control objective is to regulate the cooling rate profile at a given location, given by $C_r(\delta) = -\frac{\partial U(x, t)}{\partial t}|_{x=\delta}$. There has been, as yet, no reported experimental demonstration of open- or closed-loop control of cooling rate.

Directed Energy Deposition: Laser Metal Deposition (LMD)

Laser metal deposition (LMD) is an AM process that uses a laser beam to form a melt pool on

a metallic substrate into which metal powder is injected using a gas stream. The absorbed metal powder produces a deposit on the surface, and thus a part is created by layer-upon-layer addition of metal. For these processes, the laser power and velocity are the two controllable variables. Measured variables during the process are the height and temperature field (or melt pool size). The control objective is typically to maintain a desired layer thickness (height) and a specified melt pool size.

Melt Pool Geometry Modeling and Control

Within a single pass of the laser, i.e., a single cladding layer, the dynamics of molten-pool geometry and temperature with respect to process input parameters such as laser power and laser scan speed can be obtained from mass, momentum, and energy balance in the melt pool. This results in a nonlinear implicit ODE model of the form:

$$h^2(t)\dot{h}(t) + K_1 h^2(t)v(t) = K_2 \frac{p(t) - p_c}{T_m - T_\infty} \quad (9)$$

$$\begin{aligned} \frac{d}{dt} \left(h^3(t)e(t) \right) &= K_3 h^2(t)v(t) \\ &+ K_4 p(t) + K_5 T(t) \\ &+ K_6 T_\infty + K_7 T_m \end{aligned} \quad (10)$$

$$\begin{aligned} e(t) &= c_1 T(t) + c_2 T_m \\ &+ c_3 T_\infty, \end{aligned} \quad (11)$$

where K_i, c_i are parameters dependent on the material properties, thermal properties, and metal powder volumetric flow; $T(t)$ is the average temperature of the melt pool; T_m is the melting point of the metal powder; T_∞ is the ambient and metal substrate temperature; $h(t)$ is the clad height; $p(t)$ is the input laser power; while $v(t)$ is the laser velocity.

Based on the multi-input multi-output (MIMO) nonlinear model above, a feedback linearization control that uses laser power and

laser scan speed to simultaneously track melt pool height and temperature reference trajectories can be designed. First, (9) and (10) can be rewritten into

$$\begin{bmatrix} \dot{h}(t) \\ \dot{T}(t) \end{bmatrix} = \mathbf{f}(h(t), T(t)) + \mathbf{G}(h(t), T(t)) \cdot \begin{bmatrix} v(t) \\ \tilde{p}(t) \end{bmatrix} \quad (12)$$

where $\tilde{p} = p - p_c$. We refer the reader to Wang et al. (2016) for the detailed expressions for $\mathbf{f}$ and $\mathbf{G}$. Given measurement (or estimates) of the state, a feedback linearization control of the form

$$\begin{bmatrix} v(t) \\ \tilde{p}(t) \end{bmatrix} = \mathbf{G}^{-1} \cdot \left(-\mathbf{f} + \begin{bmatrix} \lambda_1(h_d(t) - h(t)) \\ \lambda_2(T_d(t) - T(t)) \end{bmatrix} \right) \quad (13)$$

can be used to track a reference trajectory for height and melt pool temperature $[h_d(t) \ T_d(t)]^T$.

Modeling Layer-to-Layer Height Evolution

The model above focuses on dynamics within a single layer and thus ignores layer-to-layer height evolution and the effect of stand-off height on the material catchment efficiency η , which is necessary to describe phenomena observed in LMD such as layer rippling. To capture such phenomena, a 2D model that incorporates both in-layer and layer-to-layer dynamics is necessary. In Sammons et al. (2018), a 2D model of the following form is proposed and validated:

$$\begin{aligned} h(x, k) = & f_\mu(d_s(x, k) - h(x, k-1)) \lambda(x, j) \\ & * f_s(x) + h(x, k-1) * f_r(x) \end{aligned} \quad (14)$$

where k is the layer number; h is the height profile; x is the spatial coordinate; f_μ , f_s , and f_r are functions that model powder catchment, melt dynamics, and remelt dynamics, respectively; and $*$ is the convolution operation in the spatial dimension. The two controlled inputs are

λ , the powder flow rate, and d_s , the standoff height. Given this model, feedback and feedforward control strategies for powder flow rate and stand-off height can be obtained by using design tools for the general class of 2D models, which are presented in Sammons et al. (2019).

Summary and Future Directions

Control of AM systems is still in its early stages, with significant opportunities for improvement. Given the ever-growing variety in the types of processes, feedback and feedforward control strategies will need to be developed to improve throughput and yield. There are several challenges that hinder the widespread adoption of AM control strategies, particularly for closed-loop control. These include:

- *Sensing* is particularly challenging for AM systems. Although there are several modalities for process monitoring, these are not always well-suited for real-time feedback control. Further, relating physical process variables (e.g., temperature fields) to the sensed variables (e.g., IR camera images) is often difficult. From a control standpoint, this translates to designing suitable estimation algorithms for AM processes, which remains an open question.
- Suitable *control-oriented modeling* strategies that exploit both physical models and input-output data will be critical for feedback control. Current strategies are either black box or purely physics-based, which limits their applicability.
- *Control design strategies for distributed parameter systems* (such as PDEs) will need to be developed for both polymer and metal AM processes. Current approaches for AM control rely on discretization of these models, which leads to poor guarantees of performance. Further, system identification and online adaptation of such models on the fly remain an unsolved problem.

Abstract

Since the introduction of erythropoiesis-stimulating agents (ESAs) in the late 1980s, anemia in hemodialysis (HD) patients has been managed using standard protocol-based approaches. Aiming for personalized therapy, the development of model-based feedback control algorithms for ESA dosing has become an active research area. Physiology-based models and artificial neural networks have been applied. Both approaches have shown superiority over traditional dosing schemes. In this chapter, we provide control-relevant background information, present the state-of-the-art control algorithms, and outline corresponding clinical study results.

Keywords

Model predictive control · Physiology-based models · Artificial neural networks · Erythropoiesis · Clinical trials

Introduction

In most countries worldwide, in-center hemodialysis (HD) is the predominant form of kidney replacement therapy for patients with end-stage renal disease (ESRD) (USRDS 2019). During HD, a patient's blood is filtered through an external circuit to remove waste, toxins, and excess fluids. Typically, in-center HD patients undergo treatment three times a week for about 3–5 h each. A common complication in patients with ESRD is anemia which is defined as a decreased number of circulating

red blood cells (RBCs) or decreased level of hemoglobin (Hgb). Anemia leads to reduced oxygen transport in the blood, is associated with poor quality of life, and represents an independent risk factor for cardiac disease, hospitalization, and mortality. The main driver of anemia in these patients is insufficient endogenous erythropoietin (EPO) production together with shortened RBC survival and iron deficiency. Exogenous replacement of EPO with erythropoiesis-stimulating agents (ESAs) in combination with iron supplementation has become the primary treatment. As dialysis lines provide an easy access to a patient's circulation, intravenous ESA and iron administrations during HD sessions are standard. Note that potential iron deficiency is usually assessed before initiating ESA treatment as the latter can only be efficient under sufficient iron availability (Fishbane and Spinowitz 2018; KDIGO 2012). Research in the field of personalized anemia management has so far mainly focused on the individualized dosing of ESAs, whereas iron is prescribed following computer-implemented or written protocols. Therefore, the focus of this chapter is on personalized ESA dosing.

The introduction of ESAs in the late 1980s has revolutionized the management of anemia in patients suffering from ESRD. Prior to their market entrance, RBC transfusions were the only treatment option. The currently available ESAs differ significantly in their serum half-life. First-generation drugs, epoetin alfa, are short-acting drugs as their half-life is only 4–10 h, requiring frequent dosing up to three times per week (i.e., each dialysis session). Second-generation ESAs, darbepoetin alfa and methoxy polyethylene glycol-epoetin beta, have a longer half-life of around 24–26 and 120–130 h, respectively. The benefit of the long-acting drugs is a reduction of dosing frequency from per treatment to weekly, biweekly, or even monthly (Fishbane and Spinowitz 2018; Kalantar-Zadeh 2017; Rosati et al. 2018). According to the most recent USRDS report (USRDS 2019), US HD patients were prescribed the following in 2016: 34.4% epoetin alfa, 17.9% darbepoetin alfa, and 24.4% methoxy polyethylene glycol-epoetin beta.

Anemia is assessed by a patient's Hgb level. Conventionally, Hgb concentrations in HD patients are measured between once a week and once a month from pre-dialysis blood samples. Several authors pointed at the potential of (optical) sensors like the Crit-Line® monitor (Fresenius Medical Care, Concord, CA) to provide noninvasive Hgb measurements for every HD treatment (even intra-dialysis measurements) (Chesterton et al. 2005; Thakuria et al. 2011). But until now, these additional measurements have not found their way into anemia management in clinical practice. Solely, Fuertinger et al. (2018a) used such noninvasive Hgb measurements to adapt a physiology-based mathematical model of erythropoiesis to individual patients for prediction of Hgb levels.

During the last 30 years, guidelines for Hgb targets in HD patients have been updated several times (Kalantar-Zadeh 2017; Wish 2018). Consensus exists with respect to only partially correcting anemia. It is not clear to what extent a full correction can further improve quality of life (QoL), whereas an increased risk of death and serious cardiovascular events has been demonstrated (Besarab et al. 1998; Drüeke et al. 2006; Singh et al. 2006; Pfeffer et al. 2009). At present, the recommended Hgb target range is 10–12 g/dl (Locatelli et al. 2013; Mactier et al. 2011). The most recent KDIGO anemia guidelines recommend to exceed the limit of 11.5 g/dl only for patients with further enhancement in QoL and who are prepared to take the associated risks (KDIGO 2012). This recommendation would culminate in an individualized risk versus benefit analysis for each and every patient (Drüeke et al. 2006; Fishbane and Spinowitz 2018). Koulouridis et al. (2013) have shown an association of high ESA doses with all-cause mortality and cardiovascular complications independent of Hgb. The FDA recommends using the lowest ESA dose sufficient to reduce the need for RBC transfusions. Although most patients respond adequately to ESAs, about 10% of them present ESA resistance or hyperresponsiveness (Johnson et al. 2007). These patients do not achieve the desired Hgb concentration despite large ESA

doses or require increasingly higher ESA doses to maintain a certain Hgb concentration. Hence, these patients need to be treated with caution, avoiding ineffective high ESA doses.

To summarize, the objective of anemia management in HD patients is to achieve the narrow Hgb target range while keeping ESA doses low. In addition, the individualized setting of Hgb targets should be possible. To date, there exists no generally accepted dosing algorithm. In the following, the current standard of care in ESA dosing is outlined before the two main streams in research on feedback control-based ESA dosing are presented.

Standard of Care for ESA Dosing

Most dialysis facilities use their own ESA dosing protocols which are built upon the package insert and follow human expert-based rules for initiation and dose adjustment. Usually, the last Hgb measurement and the rate of Hgb change are used to alter ESA dose recommendations between once a week and once a month. Eventually, the patient's iron status and treatment are factored in. Examples of such protocols can be found, for example, in Brier et al. (2018) and McCarthy et al. (2014). By now, these systems are usually computer-implemented which led to a certain standardization of care. So generated ESA doses are not automatically prescribed but assessed first by an anemia manager or physician who accepts or overwrites the recommendation.

The weakness of these protocols is that they are so-called one-size-fits-all and neither account for intraindividual nor interindividual variability. According to the Dialysis Outcomes and Practice Patterns Study, in June 2019, only 63% of US HD patients had a Hgb within 10–11.9g/dl (DOPPS 2019). Moreover, it has been shown that these protocols themselves contribute or even cause Hgb variability (Berns et al. 2003; Chait et al. 2013; Fishbane and Berns 2005; Rogers et al. 2018) and cycling (Lacson Jr et al. 2003), phenomena that are independently associated with all-cause mortality (Zhao et al. 2019). A virtual

anemia trial strategy to compare different dosing protocols *in silico* was presented and realized for methoxy polyethylene glycol-epoetin beta by Fuerterer et al. (2018b).

In the following, we refer to such standard treatment protocols as STPs.

Personalized ESA Dosing Through Closed-Loop Control

Different controller schemes have been developed by various groups over the last years (Barbieri 2016; Brier et al. 2010; Gaweda et al. 2014; Lines et al. 2011; Lobo et al. 2020; McCarthy et al. 2014; Uehlinger et al. 1992). This section covers approaches that have already been tested in clinical trials or even been implemented in clinical routine. As for STPs, generated ESA doses are presented to an anemia manager or physician as suggestion for prescription, turning any of the developed tools into a decision support system.

State-of-the-art feedback control algorithms for ESA dosing are model predictive controllers (MPCs) consisting of two main components: a model to predict a patient's Hgb response to ESA administration and a dose optimizer that determines, using the predictive model, optimal next ESA doses on a finite horizon into the future (called the prediction horizon). New ESA dose recommendations are triggered by Hgb measurements. The measurement frequency differs between once a week and once a month. The dosing frequency also varies between 3 times per week, weekly, biweekly, and monthly for different types of ESA. Depending on these schedules, some of the algorithms are m -step MPC schemes. The developed MPC algorithms can be categorized into two groups based on the predictive model they use: physiology-based models and artificial neural networks (ANN).

MPC Algorithms Based on Physiological Models

The physiological process that determines a patient's Hgb response to ESA administration is erythropoiesis which is the development from

multipotent hematopoietic stem cells to mature RBCs through a series of proliferations and differentiations. A schematic of erythropoiesis is given in Fig. 1. Erythropoiesis occurs mostly in the bone marrow and ends in the blood stream. Starting from hematopoietic stem cells, erythroid cells mature to BFU-Es (burst-forming unit-erythroids) which develop into CFU-Es (colony-forming unit erythroids), pass different stages of erythroblasts, and become reticulocytes. Those are released from the bone into the blood stream and mature into erythrocytes within 1–3 days. The schematic shows the approximate time that cells stay in the respective class. It becomes obvious that an estimation on the RBC response to ESA administration is difficult as the cells stay in the bone marrow for up to three weeks. The shortened RBC lifespan in HD patients was measured by Ma et al. (2017) to be 73.2 ± 17.8 days (range 37.7–115.8 days).

Initially, simplified predictive modeling approaches for ESA dosing were investigated. The very first technique was presented by Uehlinger et al. in 1992. The software package NONMEM was used to estimate the population's RBC lifespan and sensitivity to the administered ESA. Easy calculations were provided to

determine the initial dose for a single patient using the population averages and to estimate the patient's individual values over time.

Using a modification of the model proposed by Uehlinger et al. (1992), Gaweda, Brier, and others developed a multiple MPC algorithm (Gaweda et al. 2014, 2018) that is meanwhile licensed by Dosis Inc. as Strategic Anemia Advisor (SAA). The two corresponding clinical studies are listed in Table 1. The algorithm uses five preset dose-response categories (hyporesponder to extreme hyperresponder) with a representative model for each class. On a monthly basis, optimal ESA doses for the category-specific models are determined. The suggested dose is obtained as the weighted average of these five doses. The weights are calculated using a fuzzy set approach (fuzzy membership functions).

An MPC algorithm that uses an extensive physiology-based model is the Mayo Clinic Anemia Management System (MCAMS) (McCarthy et al. 2014; Rogers et al. 2018). Erythropoiesis is described by means of a two-compartment model with nonlinear first-order differential equations. A conceptual overview of the model is shown in Rogers et al. (2018), but the explicit system

equations have not been published. The dosing scheme has initially been tested in an observational study encompassing a total of 300–342 patients (see Table 1). The following five model parameters are weekly updated (if necessary) on a per patient level using a modified Monte Carlo procedure: mean daily BFU-E production rate, reference probability of CFU-E survival, effect of fractional EPO receptor binding on CFU-E survival, reticulocyte survival, and RBC lifespan (Rogers et al. 2018). Mayo Clinic licensed its algorithm to Physician Software Systems yielding FDA clearance in December 2013.

The dose optimizer applied in the study by McCarthy et al. (2014) was a simple trial-and-error strategy. So far, only in silico results for an MPC scheme that uses an individualized physiology-based model and an actual optimization algorithm for dose calculation are published (Rogg et al. 2019). The MPC scheme presented in Rogg et al. (2019) is based on a comprehensive age-structured cell population model to describe

erythropoiesis by means of partial differential equations (Fuerterer et al. 2013, 2018a). The further developed MPC algorithm is currently being tested in a clinical trial for administration of methoxy polyethylene glycol-epoetin beta (Renal Research Institute 2020).

MPC Algorithms Based on Artificial Neural Networks

ANNs are a class of nonlinear machine learning methods inspired by neurons (nerve cells) in the human brain. ANNs map a set of input variables to a corresponding target output through a series of hidden layers. The ANNs used for prediction of Hgb values are mostly so-called feed-forward ones. In Fig. 2, such an ANN is exemplified. It consists of an input layer to bring the initial data into the system, an output layer that produces the output, and one or several hidden layers in between. Each layer consists of a number of artificial neurons which are connected

Control of Anemia in Hemodialysis Patients,

Fig. 2 Example of a feed-forward artificial neural network to predict the Hgb concentration in one month time using two hidden layers

by weighted links (synapses). Each link has a numerical weight associated with it. A neural network learns through iterative adjustment of these weights which is done in the training phase where the ANN is presented with the input-output pairs from a training data set. Once trained, an ANN is tested for accuracy on unseen data from a testing set. The output value of the ANNs is the predicted Hgb value in one month time.

The first clinical results of MPC algorithms that use an artificial neural network as the predictive model have been published by [Gaweda et al. in 2008](#) and by [Brier et al. in 2010](#). While these approaches used solely Hgb and ESA information as inputs to the ANN, Barbieri et al. have developed a model that makes use of a variety of patient information given for HD patients. As these patients are usually treated three times a week, a lot of data is captured even for an individual patient. As of today, the results from two clinical studies using the developed so-called Anemia Control Model (ACM) for dosing of darbepoetin alfa have been published ([Barbieri et al. 2016b](#); [Bucalo et al. 2018](#)) (see Table 1). Results on the predictive performance of the ANN can be found in [Barbieri et al. \(2015, 2016a\)](#). In [Barbieri et al. \(2016a\)](#), the ANN is described to consist of two hidden layers with ten neurons each. The ANN was trained on almost 170,000 and tested on more than 40,000 patient data sets. This data was extracted from Nephro-Care's proprietary clinical management system EuCliD® (European Clinical Database). Today, ACM is integrated into that system. The input

parameters of the ANN include sex, height, dry weight, previous Hgb change, ESA doses from last three months, iron doses, ferritin, and others. Each Hgb measurement, which happens usually once a month, triggers a dose recommendation. According to the authors, the dose optimizer simulates the Hgb response for different ESA doses and chooses a dose that moves the Hgb into the target interval while avoiding excessive Hgb excursion downward or upward.

Summary and Future Directions

Clinical studies on MPC-guided ESA dosing in HD patients have demonstrated its benefit over traditional dosing protocols. Both approaches, MPC based on a physiology-based model of erythropoiesis and based on an ANN to predict Hgb response, have shown a better achievement of Hgb targets, reduced Hgb variability, and reduced ESA consumption. These tools render the individualized setting of Hgb targets possible. So far, none of the different approaches have been tested against each other, and all methods have been developed and tailored to a prevalent Hgb measurement frequency (weekly or monthly). Until now, no clinical results on personalized dosing of methoxy polyethylene glycol-epoetin beta have been published.

In the United States, two web-based clinical decision support tools built upon MPCs that use a physiology-based model are commercially available: Dosis Inc.'s SAA and PhySoft AMS™. The

presented ACM based on an ANN is integrated in the clinical management system EuCliD[®] but not publicly available as stand-alone tool.

Aside from that, hypoxia-inducible factor prolyl hydroxylase inhibitors (HIF-PHIs), also known as HIF stabilizers, are a new class of drugs to treat anemia in HD patients which are about to enter the markets. Roxadustat, being developed by FibroGen, is already approved in China and Japan for treatment of HD patients and was accepted by the FDA for review in February 2020. HIF-PHIs are small molecules administered orally that could change the entire paradigm of anemia management in ESRD patients. HIF-PHIs increase RBC production by stimulating not only the production of endogenous erythropoietin but also by improving iron availability. So far, large-scale clinical trials that address the long-term safety of HIF-PHIs in ESRD patients are pending. Whether HIF-PHIs are associated with less risks than ESAs at comparable target Hgb levels is not yet clear but might again shift optimal Hgb levels in HD patients.

Control of Biotechnological Processes

Rudibert King

Technische Universität Berlin, Berlin, Germany

Abstract

Closed-loop control can significantly improve the performance of bioprocesses, e.g., by an

increase of the production rate and yield of a target molecule or by guaranteeing reproducibility of the production together with low by-product formation. In contrast to control of chemical reaction systems, the biological reactions take place inside cells which constitute highly regulated, i.e., internally controlled systems by themselves. As a result, through evolution, the same cell can and will mimic a system of first order in some situations and a high-dimensional, highly nonlinear system in others. This makes supervision, control, and optimization of biosystems very demanding, and a significant amount of control design effort has to be put in the mathematical modeling in the first place.

Keywords

Bioprocess control · Control of uncertain systems · Optimal control · Parameter identification · State estimation · Structure identification · Structured models · Machine learning

Introduction

Biotechnology offers solutions to a broad spectrum of tasks faced today, e.g., in health care, remediation of environmental pollution, new sources for energy supplies, sustainable food production, and the supply of bulk chemicals. To explain the needs for control of bioprocesses, especially for the production of high-value and/or large-volume compounds, it is instructive to have a look on the development of a new process. If a potential strain is found or genetically engineered, the biologist will determine favorable environmental factors for the growth of the cells and the production of the target molecules. These factors typically comprise the kind of nutrients, precursors and so-called trace elements, and the levels of “physical” quantities such as temperature, pH, dissolved oxygen, etc. Moreover, favorable concentration regions for the different chemical compounds are specified. Whereas for the physical variables often fixed

setpoints are suggested, which, at least in smaller scale reactors, can be easily maintained by independent, classically designed controllers, information about the best nutrient supply is incomplete from a control engineering point of view. A dynamic evolution of the nutrient supply, however, offers substantial room for production improvements by control, but is most often not revealed in the biological laboratory. Even if constant concentration levels of the individual nutrients are suggested, the exponential growth of the cells and the highly nonlinear dependencies necessitate constantly changing nutrient feeds into the fermenter, posing challenges for control.

Irrespective whether bacteria, yeasts, fungi, or animal cells are used for production, these cells will consist of thousands of different compounds which react with each other in hundreds or more reactions. All reactions are tightly regulated on a molecular and genetic basis; see “Biosystems and Control”. For so-called unlimited growth conditions, all cellular compartments will be built up with the same specific growth rate, meaning that the cellular composition will not change over time. In a mathematical model describing growth and production, now only one state variable will be needed to describe the biotic phase. This will give rise to unstructured models; see below. Whenever a cell enters a limitation or the environmental conditions are changed significantly, which is often needed for production, the cell will start to dynamically reorganize its internal reaction pathways. Model-based approaches of supervision and control based on unstructured models are now bound to fail. More biotic state variables are needed in the model. However, it is not clear which and how many. As a result, modeling the behavior of the cells when the environment changes drastically is crucial for control of biotechnological processes.

For supervision and control, model-based estimates of the state of the cell and of the environment are a key factor as online measurements of the internal processes inside the cell and of part of the nutrient concentrations are usually impossible. This situation is alleviated though through progress in spectroscopic methods (see Voss et al. 2017), but care has to be taken as very often linear

methods, such as Partial Least Squares (PLS), are applied that might lead to erroneous results. An example will be given below by means of Fig. 1.

Finally, as models used for process control have to be limited in size and thus only give an approximative description, robustness of the methods has to be addressed. Due to these inherent problems, an increasing number of data-driven approaches, e.g., from machine learning, have been proposed. However, data-driven methods suffer from deficiencies with respect to predictions and transfer of control solutions when it comes to the scale-up of fermenters. Hybrid approaches may offer an attractive alternative; see below.

Mathematical Models

In bioprocesses, many up- and downstream unit operations are involved besides the fermentation. As these pose no typical bio-related challenges, we will concentrate here on the cultivation of the organisms only. This is mostly performed in aqueous solutions in special bioreactors/fermentors through which in many cases air is sparged for a supply with oxygen. Disregarding wastewater treatment plants, most cultivations are still performed in a fed-batch mode, meaning that a small amount of cells and part of the nutrients are put into the reactor initially. Then, more nutrients and correcting fluids, e.g., for pH or antifoam control, are added with variable rates leading to an unsteady behavior (see Mears et al. 2017). The system to be modeled consists of the gaseous, the liquid, and the biotic phase inside the reactor. For the former ones, balance equations can be formulated readily. The biotic phase can be modeled in a structured or unstructured way. Moreover, as not all cells behave similarly, this may give rise to a segregated model formulation that is omitted here for brevity.

Unstructured Models

If the biotic phase is represented by just one state variable, m_X , a typical example of a simple unstructured model of the liquid phase derived from balance equations would be

$$\dot{m}_X = \mu_X m_X$$

$$\dot{m}_P = \mu_P m_X$$

$$\dot{m}_S = -a_1 \mu_X m_X - a_2 \mu_P m_X + c_{S,feed} u$$

$$\dot{m}_O = a_3(a_4 - c_O) - a_5 \mu_X m_X - a_6 \mu_P m_X$$

$$\dot{V} = u$$

with the masses m_i with $i = X, P, S, O$, for cells, product, limiting substrate or nutrient, and dissolved oxygen, respectively. The volume is given by V , and the specific growth rate and production rate μ_X and μ_P depend on concentrations $c_i = m_i/V$, e.g., of the substrate S or oxygen O . The rates are described by formal kinetics, such as

$$\mu_X = \frac{a_7 c_S c_O}{(c_S + a_8)(c_O + a_9)},$$

$$\mu_P = \frac{a_{10} c_S}{a_{11} c_S^2 + c_S + a_{12}}$$

The nutrient supply can be changed by the feed rate $u(t)$ as a control input, with inflow concentration $c_{S,feed}$. Very often, just one feed stream is considered in unstructured models. As all parameters a_i have to be identified from noisy and infrequently sampled data, a low-dimensional nonlinear uncertain model results. Implicitly it is often assumed that experiments are reproducible. However, biological variance and all uncertain steps in the so-called precultures add to the uncertainty of the measured data; cf. Fig. 1.

Whereas the balance equations follow from first principles-based modeling, the structure of the kinetics μ_X and μ_P is unknown. Empirical relations are postulated. Many different kinetic expressions can be used here; see Bastin and Dochain (2008) or a small selection shown in Table 1.

It has to be pointed out that, most often, neither c_X , c_P , nor c_S are measured online. As the measurement of c_O might be unreliable, the exhaust gas concentration of the gaseous phase is the main online measurement that can be used employing an additional balance equation for the gaseous phase. Infrequent at-line measurements,

though, are available for X , P , S , especially at the lab-scale during process development.

Structured and Hybrid Models

In structured models, the changing composition and reaction pathways of the cell is accounted for. As detailed information about the cell's complete metabolism including all regulations is missing for the majority if not all cells exploited in bioprocesses, an approximative description is used. Examples are models in which a part of the real metabolism is described on a mechanistic level, whereas the rest is lumped together into one or very few states (Goudar et al. 2006) or in so-called cybernetic models (Ramkrishna and Song 2012) or in compartment models (King 1997). As an example, all compartment models can be written down as

$$\dot{\mathbf{m}} = \mathbf{A}\boldsymbol{\mu}(\mathbf{c}) + \mathbf{f}_{in}(\mathbf{u}) + \mathbf{f}_{out}(\mathbf{u})$$

$$\dot{V} = \sum_i u_i$$

with vectors of streams into and out of the reaction mixture, $\mathbf{f}_{in}$ and $\mathbf{f}_{out}$, which depend on control inputs $\mathbf{u}$; a matrix of (stoichiometric) parameters, $\mathbf{A}$; a vector of reaction rates $\boldsymbol{\mu} = \boldsymbol{\mu}(\mathbf{c})$; and, finally, a vector $\mathbf{m}$ comprising the masses of substrates, products, and more than one biotic state. These biotic states can be motivated, for example, by physiological arguments, describing the total amounts of macromolecules in the cell, such as the main building blocks DNA, RNA, and proteins. In very simple compartment models, the cell is only divided up into what is called active and inactive biomass. Again, all coefficients in $\mathbf{A}$ and the structure and the coefficients of all entries in $\boldsymbol{\mu}(\mathbf{c})$ (see Table 1) are unknown and have to be identified based on experimental data. Issues of structural and practical identifiability are of major concern. For models of system biology, algebraic equations are added that describe the dependencies between individual fluxes; however, very often information concerning the regulated dynamics of the fluxes is unknown.

Control of Biotechnological Processes, Fig. 1 EKF prediction (solid red line) of a yeast cultivation based on misleading spectroscopic data (solid black line), 2σ uncertainty interval obtained by the EKF (dotted grey line)

and off-line data (circles with error bars). Nutrients are ammonia, glucose, and phosphate. Products are ethanol and an enzyme (not shown) (Krämer and King 2016)

In hybrid models, models based on balance equations are combined with data-driven approaches, e.g., by replacing unknown parts, such as the formal kinetics of Table 1, with the outcome of neural nets; cf. (Stosch et al. 2016).

Identification

Even if the growth medium initially “only” consists of some 10–20 different, chemically well-defined substances, from which only few are described in the model, this situation will

Control of Biotechnological Processes, Table 1 Multiplicative rates depending on several concentrations $c_1, \dots, c_k$ with possible kinetic terms

$\mu_i = a_{imax} \mu_{i1}(c_1) \cdot \mu_{i2}(c_2) \cdot \dots \cdot \mu_{ik}(c_k)$			
μ_{ij}	$\frac{c_j}{c_j + a_{ij}}$	$\frac{a_{ij}}{c_j + a_{ij}}$	$\frac{c_j}{c_j^2 + a_{ij}}$
	$\frac{c_j}{c_j + a_{ij}} e^{-c_j/a_{ij+1}}$	$\frac{c_j}{a_{ij}c_j^2 + c_j + a_{ij+1}}$	$\dots$

change over the cultivation time as the organisms release further compounds from which only few may be known. If, for economic reasons, complex raw materials are used, even the initial

composition is unknown. For structured models, intracellular substances have to be determined additionally. These are embedded in an even larger matrix of compounds making chemical analysis more difficult. Therefore, the basis for parameter and structure identification or training of data-driven approaches is uncertain and sparse.

As the expensive experiments and chemical analysis tasks are very time-consuming, methods of optimal experimental design should always be considered in biotechnology; see ► [“Experiment Design and Identification for Control”](#).

The models to be built up should possess some predictive capability for a limited range of environmental conditions. This rules out unstructured models for many practical situations. However, for process control, the models should still be of manageable complexity. Medium-sized structured models seem to be well suited for such a situation. The choice of biotic states in **m** and possible structures for the reaction rates μ_i , however, is hardly supported by biological or chemical evidence. As a result, a combined structure and parameter identification problem has to be solved. The choices of possible terms μ_{ij} in all μ_i give rise to a problem that exhibits a combinatorial explosion. Although approaches exist to support this modeling step (see Herold and King 2013 or Mangold et al. 2005), the modeler will finally have to settle with a compromise with respect to the accuracy of the model found versus the number of fully identified model candidates. As a result, all control methods applied should be robust in some sense.

Soft Sensors

Despite advantages in the development of online measurements (see Mandenius and Titchener-Hooker 2013), systems for supervision and control of biotechnical processes often include model-based estimations schemes, such as extended Kalman filters (EKF); see ► [“Kalman Filters”](#) and Fig. 2. Concentration estimates are needed for unmeasured substances and for quantities which depend on these concentrations

like the growth rate of the cells. In real applications, formulations have to be used which account for delays in laboratory analysis of up to several hours and for situations in which results from the laboratory will not be available in the same sequence as the samples were taken. This can be tackled, e.g., with moving horizon estimation. An example from a real cultivation is shown in Fig. 1 where a linear spectroscopic method predicts a non-zero glucose concentration in the second half of the experiment that can be falsified by the outcome of an extended Kalman filter based on a process model. The estimates could be verified later by offline measurements shown as well.

Control

Besides the relatively simple control of physical parameters, such as temperature, pH, dissolved oxygen, and carbon dioxide concentration, only few biotic variables are typically controlled with respect to a setpoint; see Pörtner et al. (2017). The most prominent example is the growth rate of the biomass with the goal to reach a high cell concentration in the reactor as fast as possible. For non-growth-associated products, a high cell mass is desirable as well, as production is proportional to the amount of cells. If the nutrient supply is maintained above a certain level, unlimited growth behavior results, allowing the use of unstructured models for model-based control. An excess of nutrients has to be avoided, though, as some organisms, like baker's yeast, will initiate an overflow metabolism, with products that may be inhibitory in later stages of the cultivation. For some products, such as the antibiotic penicillin, the organism has to grow slowly to obtain a high production rate. For these so-called secondary metabolites, low but not vanishing concentrations for some limiting substrates are needed. If setpoints are given for these concentrations instead, this can pose a rather challenging control problem. As the organisms try to grow exponentially, the controller must be able to increase the feed exponentially as well. The difficulty mainly arises from the inaccurate and infrequent measurements

Control of Biotechnological Processes, Fig. 2 MPC control and state estimation of a cultivation with *S. tendae*. At-line measurement m_X (red filled circles), initially predicted evolution of states (black), online estimated evolution

(blue); off-line data analyzed after the experiment (open red circles). Off-line optimal feeding profiles u_i (blue broken line), MPC-calculated feeds (black, solid). Data obtained by T. Heine

that the soft sensors/controller has to work with and from the danger that an intermediate shortage or oversupply with nutrients may switch the metabolism to an undesired state of low productivity.

For control of biotechnical processes, many methods explained in this Encyclopedia including feedforward, feedback, model-based, optimal, adaptive, fuzzy, neural nets, etc., can be and have been used (cf. Rani and Rao 1999; Dochain 2008; Mears et al. 2017). As in other areas of application, (robust) model-predictive control schemes (MPC) (see ► [Model Predictive Control in Practice](#)) are applied with great success in biotechnology. One of the very first applications in which the production of an antibiotic by a mycelial organism was optimized in a 50 L scale fermenter exploiting a structured model,

an extended Kalman filter and an NMPC was already reported in the year 1993 (see King 1997; Waldruff et al. 1997). For the antibiotic production shown in Fig. 2, optimal feeding profiles u_i for the nutrients ammonia (AM), phosphate (PH), and glucose (C) were calculated before the experiment was performed (see Kawohl et al. 2007). The goal was a maximization of the final mass of the desired antibiotic nikkomycin (Ni). This resulted in the blue broken lines for the feeds u_i . However, due to disturbances and model inaccuracies, an MPC scheme had to significantly change the feeding profiles, to actually obtain this high amount of nikkomycin; see the feeding profiles given in black solid lines. This example shows that, especially in biotechnology, offline trajectory planning has to be complemented by closed-loop concepts.

Summary and Future Directions

Advanced process control including soft sensors can significantly improve biotechnical processes. Improved control in the sense of quality by design (QbD) reduces costly tests of the end product in pharmaceutical applications; cf. (Sommeregger et al. 2017). Using these techniques promotes quality and reproducibility of processes. These methods should, however, not only be exploited in the production scale. For new pharmaceutical products, the time to market is the decisive factor. Methods of (model-based) monitoring and control can help here to speed up process development. Since a few years, a clear trend can be seen in biotechnology to miniaturize and parallelize process development using multi-fermenter systems and robotic technologies. This trend gives rise to new challenges for modeling on the basis of huge data sets and for control in very small scales. At the same time, it is expected that a continued increase of information from bioinformatic tools will be available that has to be utilized for process control as well. Going to large-scale cultivations adds further spatial dimensions to the problem. Now, the assumption of a well-stirred, ideally mixed reactor does not longer hold. Substrate concentrations will be space-dependent. Cells will experience dynamically varying nutrient environments. Thus, mass transfer has to be accounted for, leading to partial differential equations as models for the process.

Control of Circadian Rhythms and Related Processes

A. Agung Julius

Department of Electrical, Computer, and Systems Engineering, Center for Lighting Enabled Systems and Applications, Rensselaer Polytechnic Institute, Troy, NY, USA

Abstract

Circadian rhythms are cyclical behaviors observed in many biological processes, which form a mechanism with which living beings can synchronize with the light and dark pattern of the terrestrial day. In humans, the suprachiasmatic nucleus (SCN) functions as the central circadian pacemaker. Misalignment between the circadian rhythms and the solar day, for example, in the case of jetlag or rotating shift work, leads to negative health consequences and lower productivity. The central circadian pacemaker is driven by light stimuli and coupled with other physiological processes. The sleep process, for example, is known to be modulated by the central circadian rhythm. In this chapter, we discuss the formulation of various control problems related to the regulation of circadian rhythms using light as the control input. We aim at shifting the phase of the circadian oscillation as quickly as possible. In some cases, we include constraints that involve sleep scheduling. In all cases, the problems are formulated as continuous-time optimal control problems.

Circadian Rhythms Entrainment

Introduction

The circadian rhythms in humans function as a master clock that regulates various biological processes such as sleep, metabolism, and neurobehavioral processes (Foster and Kreitzman 2017) (see illustration in Fig. 1). Disruption of the circadian rhythms is known to have negative impacts on health, ranging from fatigue in travelers with jetlag to an increased risk of cancer in rotating shift workers. Further, malalignment of the circadian phase and related neurobehavioral states, such as alertness, with the timing of critical tasks may lead to lower performance and higher risk of failure. The circadian rhythms are driven by internal pacemakers and externally affected by light stimuli, as well as activity, meals, body temperature, and hormones.

The sleep process in humans is very tightly connected to the circadian rhythm. The sleep drive, for example, is known to be modulated by the circadian rhythm (Achermann and Borbély 2003). Sleep is very important as it allows the body to recuperate and regenerate cells. It is also tied to neurocognitive performance; the lack of or mistiming of sleep have been empirically linked to degeneration of neurocognitive performance and disruption of circadian rhythm regulation.

Regulation of circadian rhythms, from the perspective of control systems, is typically expressed as an optimal control problem of a system with nonlinear dynamics. The control inputs into the system are typically light (Doyle III et al. 2006; Serkh and Forger 2014; Qiao et al. 2017) (which is a strong circadian synchronizer) and pharmaceuticals (Abel et al. 2019). For the remainder of this entry, we shall focus on light as the control input in circadian rhythms control.

Modeling

In the literature, there are mathematical models that capture the dynamics of the circadian rhythm and how light affects it. Generically, the models are ordinary differential equations of the form

$$\frac{dx}{dt} = F(x, u), \quad (1)$$

where x is the state of the circadian oscillator and u is the control input. Because light can only attain nonnegative intensity and its impact to the circadian oscillator has a saturation regime, u is typically constrained as

$$0 \leq u(t) \leq u_{\max}, \quad (2)$$

for all $t \geq 0$.

Circadian rhythms models come in various orders (i.e., levels of complexity). The highest order models, typically based on the biochemical processes in the circadian gene regulation (Leloup and Goldbeter 2003). Lower-order models are typically empirical, such as the third-order model by Jewett et al. (1999), which uses a van der Pol oscillator to represent the circadian

rhythm of the core body temperature. There are also first-order models as described below (Qiao et al. 2017).

First-order models that describe the circadian phase dynamics are of the form

$$\frac{d\theta}{dt} = \omega_0 + f(\theta)u, \quad (3)$$

where the variable θ is the circadian phase, expressed in rad. The parameter ω_0 is the so-called free-running frequency, expressed in rad/h. Nominally its value is around $\frac{2\pi}{24}$ rad/h. The variable u is the light control input. The function $f(\theta)$ is called the *phase response function* or *phase response curve*, which maps the circadian light input to the dynamics of the circadian phase.

The dynamics of the sleep and neurobehavioral states are coupled to that of the circadian rhythm. Their relationship is described in a family of models called the two-process models. These models link the dynamics of sleep drive and alertness to the circadian phase in a hybrid or multimodal dynamical system:

Control of Circadian Rhythms and Related Processes, Fig. 1 The circadian component of various physiological and neurobehavioral (e.g., alertness) processes. (Image source: https://en.wikipedia.org/wiki/Circadian_rhythm)

Control of Circadian Rhythms and Related Processes, Fig. 2 Illustration of the sleepiness trajectory, which is modeled as a hybrid system. The subject goes to sleep at time $T_1, T_3, \dots$ and wakes up at $T_2, T_4, \dots$

$$\frac{ds}{dt} = \begin{cases} G_s(s), & \text{if the subject is asleep,} \\ G_a(s), & \text{if the subject is awake.} \end{cases} \quad (4)$$

Here s denotes the sleep and neurobehavioral states. The transitions between the sleep and awake modes are determined by sleepiness. Sleepiness is quantified as a variable $B(t)$ and modeled as a function of the circadian and sleep states,

$$B(t) = H(x(t), s(t)). \quad (5)$$

The transitions between sleep and wakefulness can be modeled in two ways:

1. Autonomous switching: the occurrence of the transitions purely depends on the states of the systems. For example, we can assume that the subject falls asleep when their sleepiness reaches a certain high level and wakes up spontaneously when their sleepiness hits a certain low level.
2. Scheduled switching: the transitions are externally scheduled, for example, when the subject follows a given sleep schedule.

The hybrid nature of the two process model is illustrated in Fig. 2. Note that the sleep state impacts the circadian state dynamics because the light stimuli cannot act on the subject while asleep.

Alertness, quantified as $A(t)$, is modeled as a function of the sleep and neurobehavioral states (Achermann and Borbely 2003),

$$A(t) = K(x(t), s(t)). \quad (6)$$

The factors that impact alertness in this model are sleep debt (whether the subject is lacking sleep), sleep inertia (whether the subject just recently gain wakefulness), and circadian phase (the subject's biological clock).

Optimal Control of Circadian Rhythms and Related Processes

Quickest Entrainment Problem

One of the main problems in optimal circadian rhythm regulation is the *quickest entrainment problem*, which can be formulated as follows.

Quickest Entrainment Problem (QEP) Given the dynamics of the circadian state in Eqs. (1) and (2), an initial condition $x(0) = x_0$, and a reference circadian state trajectory $x_{\text{ref}}(t)$, determine the input $u(t)$ that minimizes the entrainment time T . Here, the entrainment time T is defined as the earliest time such that $x(T) = x_{\text{ref}}(T)$.

The quickest entrainment problem can capture, e.g., the problem of eliminating jetlag as quickly as possible. In this case, the reference $x_{\text{ref}}(t)$ is the desired circadian state trajectory (without the jetlag). QEP is, in optimal control terminology, a minimum time optimal control problem, which can be solved using, for example:

1. Calculus of variations: this approach includes optimal control techniques (Bryson and Ho 1975), resulting in both *open-loop* optimal lighting strategies (Serkh and Forger 2014), where the optimal light signal is computed offline, and *feedback* optimal lighting strategies, where the optimal light signal is computed as a function of the current circadian state (Qiao et al. 2017).
2. Model predictive control: this approach is based on optimizing the light input in a receding horizon optimization (Mott et al. 2003). However, since minimum time control problems cannot be directly posed in a

receding horizon fashion, the optimization objective is typically formulated as to minimize the error between the circadian states and their respective references.

Examples of the solutions of QEP for various jetlag cases using the third order Kronauer model (Jewett et al. 1999) are shown in Fig. 3. The trajectories of the two circadian oscillator states and their respective references (with the subscript r) are shown in each graph. The optimal light inputs follow a bang-bang control law, as is typical in minimum time control problems. Serkh and Forger (2014) exploited this assumption by computing the optimal light input by parameterizing it by the switching times between light on and light off. On the other hand, Qiao et al. (2017) use Pontryagin's Maximum Principle to compute the optimal light input.

Optimal Control Involving Neurobehavioral Dynamics

The formulation of QEP ignores the dynamics of the sleep and neurobehavioral states ($s(t)$). Therefore, the resulting optimal solutions may be impractical from the sleep perspective. To address this limitation, QEP can be modified to include the sleep dynamics. There are two variations of the new formulation, one where sleep is considered autonomous and one where sleep can be scheduled, as discussed in the previous section.

In the autonomous sleep-wake transitions case, the subject goes to sleep when their sleepiness ($B(t)$) reaches a certain high level ($B_{\max}$) and wakes up when it reaches a certain low level ($B_{\min}$). In the scheduled sleep-wake transitions case, we assume that the transitions can occur any time. However, to add realism to the model, we disallow the situation where the sleep period is too long (which is impossible in reality; the subject would spontaneously wake up), and the situation where the awake period is too long (which leads to sleep deprivation). This leads to two new versions of the quickest entrainment problem.

Quickest Entrainment Problem with Autonomous Sleep (QEP-A) Given the dynamics of the circadian, sleep, and neurobehavioral states in Eqs. (1), (2), (3), (4), and (5), where the switching of the sleep dynamics is autonomous, an initial condition $x(0) = x_0$, $s(0) = s_0$, and a reference circadian state trajectory $x_{\text{ref}}(t)$, determine the input $u(t)$ that minimizes the entrainment time T . Here, the entrainment time T is defined as the earliest time such that $x(T) = x_{\text{ref}}(T)$.

Quickest Entrainment Problem with Schedulable Sleep (QEP-S) Given the dynamics of the circadian, sleep, and neurobehavioral states in Eqs. (1), (2), (3), (4), and (5), an initial condition $x(0) = x_0$, $s(0) = s_0$, and a reference circadian state trajectory $x_{\text{ref}}(t)$, determine the input $u(t)$ and the sleep schedule that meets the scheduling constraint, such that the entrainment time T is minimized. Here, the entrainment time T is defined as the earliest time such that $x(T) = x_{\text{ref}}(T)$.

QEP-A and QEP-S are more challenging to solve compared to QEP because the associated systems dynamics (i) have higher orders and (ii) are non-smooth because of the switching. Further, QEP-S is more challenging to solve compared to QEP-A because QEP-S has more optimization variables and constraints (i.e., the sleep schedule). Both QEP-A and QEP-S can be solved using the calculus of variations (Julius et al. 2017). Samples of the solutions can be seen in Fig. 4. The circadian rhythm model used to obtain these results are the same third-order Kronauer model (Jewett et al. 1999) as in the previous subsection.

Another type of optimal control problems that involves the dynamics of the neurobehavioral processes is the alertness optimization problem. The idea is to have the subject be maximally alert during a prescribed time interval, e.g., between given T_{start} and T_{end} . Such problem can be formulated as follows.

Alertness Optimization Problem (AOP) Given the dynamics of the circadian, sleep, and neurobehavioral states in Eqs. (1), (2), (3), (4), (5),

Control of Circadian Rhythms and Related Processes, Fig. 3 Examples of QEP solutions. All simulations are run until entrainment. Cyan bands represent when the optimal control input (lighting) is on. Orange bands represent when the natural (reference) daylight is on (assuming 16 h/8 h light/dark pattern)

Control of Circadian Rhythms and Related Processes, Fig. 4 Solutions of QEP-A (top row) and QEP-S (bottom row), for various jetlag cases. All simulations are run until entrainment. Cyan bands represent when the optimal control input (lighting) is on. Orange bands represent when the natural (reference) daylight is on (assuming 16h/8h light/dark pattern). Light gray bands represent the sleep intervals of the subject. Dark gray bands represent the sleep intervals of the reference

and (6), an initial condition $x(0) = x_0, s(0) = s_0$, determine the input $u(t)$ and the sleep schedule that meets the scheduling constraint, such the minimum alertness $A_{\min}$ is maximized. Here, $A_{\min}$ is defined as

$$A_{\min} \triangleq \min_{T_{\text{start}} \leq t \leq T_{\text{end}}} A(t). \quad (7)$$

AOP can also be solved using the calculus of variations (Zhang et al. 2012). Note that further variations of the OAP can be formulated by, for example, adding the constraints on sleep scheduling.

Related Topics

Spectrally Tunable Lighting

While some of optimal solutions discussed above require turning off the circadian light for some period of time, in practice, the subject is not necessarily in absolute darkness. The circadian rhythms are known to be mostly affected by blue light (Foster and Kreitzman 2017). In practice, the computed optimal control may be implemented in spectrum-variable illumination or via spectral manipulation, e.g., by using blue-blocking filters, leading to smart spaces (e.g., hotel rooms, hospitals) that regulate the occupants' circadian rhythms.

State Estimation

The circadian states $x(t)$ are not directly measurable. Rather, we typically have measurements of indirect markers that are driven by the circadian rhythms, such as actigraphy, heart rate, and body temperature (Foster and Kreitzman 2017). Ideally, we want to estimate the system states from these measurements. A possible approach is to use first-order models that capture only the dynamics of the circadian phase $\theta(t)$. Then, we extract the periodic content of the biometric data stream, for example, by using Fourier analysis or algorithms such as the adaptive notch filter (ANF) (Julius et al. 2016). We can associate the phase shifts of these periodic signals with those of the circadian rhythms and thus use this idea

to identify the phase response curve and estimate the circadian phase.

Control of Drug Delivery for Type 1 Diabetes Mellitus

Kelilah L. Wolkowicz, Francis J.

Doyle III, and Eyal Dassau

Harvard John A. Paulson School of Engineering and Applied Sciences, Harvard University, Cambridge, MA, USA

Abstract

The automated insulin delivery (AID) device known as an artificial pancreas (AP) contains a closed-loop feedback controller that enables glucose management for those with type 1 diabetes mellitus (T1DM). The AP system is comprised of two elements: devices and software. Devices include insulin delivery devices and glucose sensors, while software includes the user interface and the control algorithm. Decision support systems (DSS) also support treatment decisions for those with diabetes mellitus if the user does not use a closed-loop system. This chapter is divided into three sections, beginning with a description of controller components, design objectives, the challenges and the limitations of AID devices. This discussion is followed by recent advances in closed-loop clinical trials, common control algorithms, and clinical challenges. Finally, general expectations for future developments within AID engineering and clinical translation are outlined.

Keywords

Automated insulin delivery · Artificial pancreas · Controller design · Clinical trials · Clinical translation · Decision support system · Qualitative comparison · Healthcare

Introduction

Type 1 diabetes mellitus (T1DM) is a disease that prevents the body from properly producing

insulin, resulting in abnormal metabolism of carbohydrates that generates elevated levels of glucose in the blood and urine (American Diabetes Association 2013). Glucose control is a complex and challenging problem. It includes tracking, rejection of both measured and unmeasured disturbances, uncertainty, and numerous safety constraints. Moreover, the addition of the human-in-the-loop can contribute to system instability, introduce further disturbances, and may initiate signal overrides.

Over 130 clinical studies have demonstrated the safety and efficacy of closed-loop systems for glucose control since 2004. These studies have included different algorithms evaluated across age groups and clinical conditions. The application of advanced control algorithms has led to advanced glycemic control, leading to reduced low-glucose events, as well as achieved tighter control (improved balance in glucose levels) overnight (Doyle et al. 2014; Bertachi et al. 2018; Kowalski 2015). However, only one AID system (Medtronic MiniMed 670G) and two semiautomated systems (Medtronic MiniMed 630G and Tandem t:slim X2 with Basal-IQ) are currently approved for use by the Food and Drug Administration (FDA) (Garg et al. 2017). These semiautomated systems are important stepping stones in the pathway toward hybrid and, ultimately, fully closed-loop systems. The design of control algorithms for a medical application is complex; the user may play an integral part in the intervention (control action) or add unmeasured disturbances. Yet, it is when humans are included in the loop that tight control and performance become even more important to ensure the safety of AID systems.

Engineering Design and Clinical Translation of Type 1 Diabetes Treatment

Preclinical and clinical aspects of AID device development prior to 2014 are summarized in Doyle et al. (2014) and Kudva et al. (2014). Since 2014, significant improvements have been

made with regard to blood glucose (BG) control, particularly in terms of moving AID systems from clinic-based trials toward those that mimic everyday life. This progress relies on identifying and defining the specific factors that pertain to this engineering design problem.

Closed-loop AID devices, such as the AP, provide a route to automate glycemic control so that little to no user intervention is required. The closed-loop system automatically computes and delivers the appropriate insulin dose to the patient, allowing the controller to maintain a desired blood glucose concentration, as illustrated in Fig. 1. First, the desired BG concentration is defined as a specific value (set point) or a target range (zone), which can be fixed or time-varying. The controller compares the desired BG with a measured BG value that is typically received via a single continuous glucose monitor (CGM) attached to the user's abdomen or arm. The controller works to minimize the difference, or error, between the desired and actual BG values. Most CGMs measure the user's actual BG every 5 minutes, resulting in a time delay between the controller's adjustment in insulin delivery and the effect in the user's blood glucose levels. A delay also results due to the time it takes insulin to reach peak serum concentration, which influences the ability to reject disturbances such as inaccuracies in meal bolus dosing, exercise, or stress (Nimri et al. 2019; Dassau et al. 2017a); otherwise the user may request more insulin than is needed (stacking insulin), which in turn may result in dangerously low-glucose levels.

The second element of the AP system is the controller. To date, the most common control algorithms used within AP systems are model predictive control (MPC), proportional-integral-derivative control (PID), and fuzzy logic control (FL). Each algorithm has tuning parameters to adjust how the controller will react to deviations in BG from the desired value. Some control algorithms also integrate insulin feedback and/or insulin-on-board (IOB) constraints to help mitigate insulin stacking. Insulin feedback accelerates the insulin profile, improving the

performance of the controller (Lee et al. 2013). IOB constraints are based on the insulin delivery history (e.g., after a meal bolus) and attempt to approximate the amount of insulin present within the body (Gondhalekar et al. 2016; Dassau et al. 2015). Various models can also be integrated with the AP controller, including physiological (e.g., glucose-insulin dynamics) or empirical models, each of which can either be static or adaptive in nature. Predictive low-glucose suspend (PLGS) is often used in semiautomated systems to suspend basal insulin delivery when low BG is predicted and resume insulin delivery once BG levels begin to rise. Once the closed-loop controller has calculated the error between the actual and desired BG level, the output of the control algorithm communicates the amount of insulin that should be delivered (known as an insulin bolus) to the user via an insulin delivery device, either an insulin pump or insulin pen.

Another important consideration is how closely a user is involved with the AP system, i.e., whether or not the user is directly involved in the control loop (*patient treatment action block*). For example, some AP designs require the user to input a meal announcement, which indicates the size of the meal consumed, allowing the controller to calculate and deliver a full or partial insulin bolus. In other AP designs, the user manually calculates and delivers their meal bolus. Manual meal boluses and/or announcements can often result in tighter control due to the delays in insulin action after delivery and glucose sensing by the controller alone. Users may also provide exercise announcements, allowing the AP to temporarily suspend insulin boluses. Potentially, additional hormones and medications may also be delivered to the user, either manually or through the automated system. These medications include pramlintide, glucagon, and oral dextrose. However, adding user involvement to control performance increases safety concerns, given the unpredictable nature of human behavior (Doyle et al. 2014). The impact of the degree of automation and control performance is critical when considering the design and primary objectives of an AP system.

user is physically active, as well as to improve the controller responsiveness to the activity and glucose trends.

In addition to sensor development, inter-device communication is imperative. Medical devices need to be robust against potential communication and connectivity issues, especially when integrating different hardware platforms. Current clinical trials are testing an AP controller that connects to the user's insulin pump via Bluetooth (Deshpande et al. 2018). This approach brings the technology closer to what the user expects in their everyday life, but frustration ensues when the connection or communication between the two devices is sporadic. Increasing the battery life of these devices is also an important factor, especially when Bluetooth or other wireless communication is needed. Embedded controllers receive CGM data and communicate with a pump and display interface for user interaction (such as a smart phone) via Bluetooth Low Energy (Deshpande et al. 2018; Chakrabarty et al. 2018). The recent push toward integrated devices with embedded controllers may lend to lowering energy costs (Chakrabarty et al. 2018). These system advances get us closer to miniaturized, low-power technology, allowing for wearable and implantable medical devices with long life expectancy (Chakrabarty et al. 2018).

Another limitation facing AP development is human physiology. The high intra- and intersubject variability in insulin kinetics and dynamics affects the estimation of insulin time-to-peak activity, as well as the metabolic clearance rate (Doyle et al. 2014; Haidar et al. 2013). For fully automated AP systems that respond exclusively to CGM feedback, such uncertainties can result in the restricted ability of the controller to respond adequately to unannounced disturbances, leading to over- or under-calculation of insulin dosing. Controllers must be sufficiently robust to these variations. Incorporating additional physiological inputs in control algorithms may result in superior glucose regulation (Doyle et al. 2014; Kudva et al. 2014). Adaptive algorithms that learn how to react to certain user characteristics over time may help to address this intra- and intersubject

variability. For example, some adaptive algorithms optimize the tuning of a user's day- to nighttime basal insulin needs, insulin sensitivity, or meal bolus information for slow inter-day variability. Other algorithms adapt to exercise based on wearable sensors (Castle et al. 2018). As machine learning and artificial intelligence-based technology become more established and suitable for clinical use, these methods may also provide powerful tools for glycemic control and management (Contreras and Vehi 2018). Finally, it must be noted that insulin cannot be removed from the body once delivered to the user. Consequently, controllers must account for IOB (Doyle et al. 2014). While the controller (or the user, manually) can correct with additional carbohydrates or glucagon, this approach may require increased consumption of insulin (Castle et al. 2018; Christiansen et al. 2017; Haidar et al. 2015).

Recent Advances in Clinical Trials

The increasing number of clinical studies lasting over 24 hours reveals the progress in analysis and performance of closed-loop AP systems (Fig. 2). Since 2014, the average percentage of closed-loop time maintained within the euglycemic range (using 70–140 mg/dL) has steadily increased to 72.4%. Additionally, the average percentage of closed-loop time within the hypoglycemic range was 2.29% (using <70 mg/dL). These studies have continued to incorporate more difficult challenges within their protocols (Fig. 3). Yet, there is still inconsistency across those protocols, with very few following the same for closed-loop initiation, meal size and timing, or exercise length and intensity (Doyle et al. 2014). In February 2017, the Advanced Technologies & Treatments for Diabetes (ATTD) Congress convened a panel to address the issue of lack of standardized metrics for analyzing CGM data (Danne et al. 2017). This conference resulted in a consensus report that identified 14 key metrics now recommended to assess and document glycemic control (Danne et al. 2017). These metrics were further updated in 2019 (Battelino et al. 2019).

Control of Drug Delivery for Type 1 Diabetes Mellitus, Fig. 2 Comparison of number of clinical trials per year, including and since 2014 and corresponding types of control algorithms used, where MPC is model predic-

tive control, PD is proportional-derivative control, PID is proportional-integral-derivative control, FL is fuzzy logic, and PLGS is predictive low-glucose suspend

Control of Drug Delivery for Type 1 Diabetes Mellitus, Fig. 3 Engineering and clinical study categories in the AP world by year. Exercise includes studies allowing free-living conditions

The largest and most imminent clinical risk to people with DM is hypoglycemia, which occurs as a result of over delivery or stacking of insulin, exercise, stress, or consumption of alcohol. An increasing amount of AP designs are incorporating safety systems to mitigate this risk, including insulin feedback, IOB calculation and penalization, low-glucose prediction, remote monitoring, and exercise detection (Rossetti et al. 2017; Pinsker et al. 2018; Forlenza et al. 2017). While several research groups have developed algorithms that incorporate insulin estimation within the control loop, no clinical trials have yet included these algorithms within their study protocol (Hajizadeh et al. 2017, 18AD). One of the major limitations is that minimally invasive and portable insulin measurement sensors are still in their infancy. Insulin measurement information has the opportunity to potentially remove the risk of insulin stacking, in addition to removing much of the burden of carbohydrate counting and the need for an insulin bolus calculator (Forlenza 2017).

To manage changes in BG levels, there are two primary routes for insulin delivery: subcutaneous (SC) and intraperitoneal (IP). SC methods receive the insulin bolus from an external insulin pump, and delivery can occur both from multiple daily injections (most common, overall) and continuous subcutaneous insulin infusion (most common for AP). IP methods, on the other hand, can receive the insulin bolus either internally or externally but require users to have an implantable pump or a intraperitoneal port (Dassau et al. 2017b). IP insulin delivery is currently the least common approach due to the requirement that patients must have an implanted catheter, but it provides faster insulin action and elimination than SC, allowing the AP controller to institute changes in glucose levels more quickly. Continuous IP insulin infusion has been demonstrated to improve glycemic control and the quality of life of those with particularly hard to manage (brittle) T1DM (van Dijk et al. 2016, 2015; Logtenberg et al. 2009).

Algorithms have also seen major enhancements. MPC and PID algorithms have continued to undergo the most extensive evaluation in

comparison to others, with 53% and 20% of studies performed, respectively (Fig. 2). Both controllers have demonstrated strong performance across all metrics, including perturbation attenuation when considering challenging disturbances. Fuzzy logic (FL) was the third most evaluated controller, used in 8% of long-term clinical studies. While PLGS algorithms were only used in 5%, they have been used in both the semiautomated systems approved for use by the FDA: Medtronic MiniMed 630G and Tandem t:slim X2 with Basal-IQ. Other control strategies constituted 14%. MPC have shown recent advancement with several specified algorithmic methodologies, including model personalization and asymmetric input cost functions. Model personalization adapts input parameters to be subject-specific, ensuring that controller suggested insulin delivery rates are limited to safety purposes (e.g., avoiding hypoglycemia) due to unique insulin sensitivities (Hajizadeh et al. 18AD; Buckingham et al. 2018). Asymmetric input cost functions decouple the design of the controller's response to hyper- and hypoglycemia because a rise of 30 mg/dL in BG is not equivalent in risk to the same drop in BG, which could be fatal (Gondhalekar et al. 2016; Dassau et al. 2015; Lee et al. 2016). The integration of each of these algorithmic methodologies improves the ability of the AP to more holistically manage an individual's changes in glucose because they compensate for realistic inter- and intra-subject variability.

In an effort to push the performance margins of the AP controller, more studies have incorporated high-impact disturbances within their protocols. Since the timing, size, and composition of meals is variable, compensating for meal disturbances is one of the most difficult challenges in glucose control. Consequently, meal challenges are incorporated to see how the AP handles meals with higher protein and/or fat content, simplified meal insulin boluses, and, most commonly, when the user does not alert the controller of a meal (unannounced meals). Over 48 closed-loop AP studies have also incorporated exercise challenges to aid the controller's ability to mitigate hypoglycemic events. This scenario can prove

especially challenging if a snack is taken pre-exercise. At the same time, an increasing number of studies mimic everyday life through outpatient or free-living assessments. In 2014, about 30% of closed-loop AP studies included outpatient protocols, since then, they have dramatically increased to 52% in 2015, 54% in 2016, 51% in 2017, 45% in 2018, and 43% in 2019.

Despite the progress in AID system control, several limitations still remain that restrict the performance of fully automated systems. User safety is the most important aspect of medical device design, followed by user convenience. Further clinical studies with a variety of participant cohorts (e.g., pediatric, pregnant, renal insufficient, and the elderly) using larger sample sizes may help to improve upon time in range (Bekiari et al. 2018). While the majority of AID systems are evaluated for T1DM, a transition to T2DM is the next step. A complete understanding about the effects of pregnancy in women with T1DM and gestational DM is not known, but these users require tight glucose control to prevent unwanted outcomes (Bertachi et al. 2018). For these users and those in urgent or critical care, adaptive control strategies may be advantageous due to the continuous changes in insulin requirement during pregnancy and illness (Bertachi et al. 2018).

Summary and Future Directions

Recent advances have improved our understanding of patients' interactions with closed-loop AID systems. In the near future, the number of closed-loop clinical AID studies and the of number of potential controller configurations will increase. Introducing advances in sensor technology within AID closed-loop systems will enable the next generation of algorithms to dramatically enhance glycemic control with added physiological information (e.g., physical activity, cortisol, and alcohol levels).

The main limitations of current AID systems are related to variability in outcome reporting, sample size, and short follow-up duration of individual trials (Bekiari et al. 2018). Further

limitations are associated with the accuracy and reliability of available CGM systems, as well as the delayed therapeutic effect of insulin when administered through the SC route. Standardizing controller evaluations and reporting performances in clinical trials will make qualitative analysis more meaningful across the various systems being tested; the adaptation to the International consensus recommended metrics will aid in clearly reporting study outcomes (Danne et al. 2017; Battelino et al. 2019). Additionally, challenges still exist in terms of user acceptance and trust when using an AID system. As stated by Deshpande et al., user trust and the accompanying psychosocial impacts of AP technology are areas that require continued improvement and study (Deshpande et al. 2018). In doing so, AID systems can continue to advance, improving the quality of life of their users.

Control of Fluid Flows and Fluid-Structure Models

Jean-Pierre Raymond

Institut de Mathématiques, Université Paul Sabatier Toulouse III and CNRS, Toulouse Cedex, France

Abstract

In this entry, some fluid models are introduced, and corresponding controllability and stabilization results are presented. A short overview on control results for fluid-structure interaction models is then given.

Keywords

Control · Stabilization · Fluid flows · Fluid-structure systems

Some Fluid Models

We consider a fluid flow occupying a bounded domain $\Omega_F \subset \mathbb{R}^N$, with $N = 2$ or $N = 3$, at the initial time $t = 0$ and a domain $\Omega_F(t)$ at time $t > 0$. Let us denote by $\rho(x, t) \in \mathbb{R}^+$ the density of the fluid at time t at the point $x \in \Omega_F(t)$ and by $u(x, t) \in \mathbb{R}^N$ its velocity. The fluid flow equations are derived by writing the mass conservation

$$\frac{\partial \rho}{\partial t} + \operatorname{div}(\rho u) = 0 \quad \text{in } \Omega_F(t), \quad \text{for } t > 0, \quad (1)$$

and the balance of momentum

$$\rho \left(\frac{\partial u}{\partial t} + (u \cdot \nabla) u \right) = \operatorname{div} \sigma + \rho f \quad (2)$$

in $\Omega_F(t)$, for $t > 0$,

where σ is the so-called constraint tensor and f represents a volumic force. For an isothermal fluid, there is no need to complete the system by the balance of energy. The physical nature of the fluid flow is taken into account in the choice of the constraint tensor σ . When the volume is

preserved by the fluid flow transport, the fluid is called incompressible. The incompressibility condition reads as $\operatorname{div} u = 0$ in $\Omega_F(t)$. The incompressible Navier-Stokes equations is the classical model to describe the evolution of isothermal incompressible and Newtonian fluid flows. When in addition the density of the fluid is assumed to be constant, $\rho(x, t) = \rho_0$, the equations reduce to

$$\begin{aligned} \operatorname{div} u &= 0, \\ \rho_0 \left(\frac{\partial u}{\partial t} + (u \cdot \nabla) u \right) &= \nu \Delta u - \nabla p + \rho_0 f \quad \text{in } \Omega_F(t), \quad t > 0, \end{aligned} \quad (3)$$

which are obtained by setting

$$\sigma = \nu(\nabla u + (\nabla u)^T) + \left(\mu - \frac{2\nu}{3}\right) \operatorname{div} u I - pI, \quad (4)$$

in (2). When $\operatorname{div} u = 0$, the expression of σ simplifies. The coefficients $\nu > 0$ and $\mu > 0$ are the viscosity coefficients of the fluid, and $p(x, t)$ is its pressure at the point $x \in \Omega_F(t)$ and at time $t > 0$. This model has to be completed with boundary conditions on $\partial\Omega_F(t)$ and an initial condition at time $t = 0$.

The incompressible Euler equations with constant density are obtained by setting $\nu = 0$ in the above system.

The compressible Navier-Stokes system is obtained by coupling the equation of conservation of mass (1) with the balance of momentum (2), where the tensor σ is defined by (4) and by completing the system with a constitutive law for the pressure.

Control Issues

There are unstable steady states of the Navier-Stokes equations which give rise to interesting control problems (e.g., maximize the lift drag ratio), but cannot be observed in real life because of their unstable nature. In such situations, we would like to maintain the physical model close to an unstable steady state by the action of a

control expressed in feedback form, i.e., as a function depending either on an estimation of the velocity or depending on the velocity itself. The estimation of the velocity of the fluid may be recovered by using some real time measurements. In that case, we speak of a feedback stabilization problem with partial information. Otherwise, if the control is expressed in terms of the velocity itself, we speak of a feedback stabilization problem with full information.

Another interesting issue is to maintain a fluid flow (described by the Navier-Stokes equations) in the neighborhood of a nominal trajectory (not necessarily a steady state) in the presence of perturbations. This is a much more complicated issue which is not yet solved.

In the case of a perturbation in the initial condition of the system (the initial condition at time $t = 0$ is different from the nominal velocity field at time $t = 0$), the exact controllability to the nominal trajectory consists in looking for controls driving the system in finite time to the desired trajectory.

Thus, control issues for fluid flows are those encountered in other fields. However there are specific difficulties which make the corresponding problems challenging. When we deal with the incompressible Navier-Stokes system, the pressure plays the role of a Lagrange multiplier associated with the incompressibility condition. Thus we have to deal with an infinite-dimensional nonlinear differential algebraic system. In the case of a Dirichlet boundary control, the elimination of the pressure, by using the so-called Leray or Helmholtz projector, leads to an unusual form of the corresponding control operator; see Raymond (2006). In the case of an internal control, the estimation of the pressure to prove observability inequalities is also quite tricky; see Fernandez-Cara et al. (2004). From the numerical viewpoint, the approximation of feedback control laws leads to very large size problems, and new strategies have to be found for tackling these issues.

Moreover, the issues that we have described for the incompressible Navier-Stokes equations may be studied for other models like the compressible Navier-Stokes equations and the Euler equations (describing non viscous fluid flows)

both for compressible and incompressible models or even more complicated models.

Feedback Stabilization of Fluid Flows

Let us now describe what are the known results for the incompressible Navier-Stokes equations in 2D or 3D bounded domains, with a control acting locally in a Dirichlet boundary condition. Let us consider a given steady state (u_s, p_s) satisfying the equation

$$- \nu \Delta u_s + (u_s \cdot \nabla) u_s + \nabla p_s = f_s,$$

and $\operatorname{div} u_s = 0$ in Ω_F ,

with some boundary conditions which may be of Dirichlet type or of mixed type (Dirichlet-Neumann-Navier type). For simplicity, we only deal with the case of Dirichlet boundary conditions

$$u_s = g_s \quad \text{on} \quad \partial\Omega_F,$$

where g_s and f_s are time independent functions. In the case $\Omega_F(t) = \Omega_F$, not depending on t , the corresponding instationary model is

$$\begin{aligned} \frac{\partial u}{\partial t} - \nu \Delta u + (u \cdot \nabla) u + \nabla p &= f_s \\ \text{and} \quad \operatorname{div} u &= 0 \text{ in } \Omega_F \times (0, \infty), \\ u &= g_s + \sum_{i=1}^{N_c} f_i(t) g_i, \quad \partial\Omega_F \times (0, \infty), \\ u(0) &= u_0 \quad \text{on } \Omega_F. \end{aligned} \tag{5}$$

In this model, we assume that $u_0 \neq u_s$, g_i are given functions with localized supports in $\partial\Omega_F$ and $f(t) = (f_1(t), \dots, f_{N_c}(t))$ is a finite-dimensional control. Due to the incompressibility condition, the functions g_i have to satisfy

$$\int_{\partial\Omega_F} g_i \cdot n = 0,$$

where n is the unit normal to $\partial\Omega_F$, outward Ω_F .

The stabilization problem, with a prescribed decay rate $-\alpha < 0$, consists in looking for a control f in feedback form, that is, of the form

$$f(t) = K(u(t) - u_s), \tag{6}$$

such that the solution to the Navier-Stokes system (5), with f defined by (6), obeys

$$\|e^{\alpha t}(u(t) - u_s)\|_Z \leq \varphi(\|u_0 - u_s\|_Z),$$

for some norm Z , provided $\|u_0 - u_s\|_Z$ is small enough, and where φ is a nondecreasing function. The mapping K , called the feedback gain, may be chosen linear.

The usual procedure to solve this stabilization problem consists in writing the system satisfied by $u - u_s$, in linearizing this system, and in looking for a feedback control stabilizing this linearized model. The issue is first to study the stabilizability of the linearized model and, when it is stabilizable, to find a stabilizing feedback gain. Among the feedback gains that stabilize the linearized model, we have to find one able to stabilize, at least locally, the nonlinear system too.

The linearized controlled system associated with (5) is

$$\begin{aligned} \frac{\partial v}{\partial t} - \nu \Delta v + (u_s \cdot \nabla) v + (v \cdot \nabla) u_s + \nabla q &= 0 \\ \text{and} \quad \operatorname{div} v &= 0 \text{ in } \Omega_F \times (0, \infty), \\ v &= \sum_{i=1}^{N_c} f_i(t) g_i \text{ on } \partial\Omega_F \times (0, \infty), \\ v(0) &= v_0 = u_0 \text{ on } \Omega_F. \end{aligned} \tag{7}$$

The easiest way for proving the stabilizability of the controlled system (7) is to verify the Hautus criterion. It consists in proving the following unique continuation result. If $(\phi_j, \psi_j, \lambda_j)$ is the solution to the eigenvalue problem

$$\begin{aligned}
& \lambda_j \phi_j - \nu \Delta \phi_j - (u_s \cdot \nabla) \phi_j + (\nabla u_s)^T \phi_j \\
& + \nabla \psi_j = 0 \quad \text{and} \quad \operatorname{div} \phi_j = 0 \text{ in } \Omega_F, \\
& \phi_j = 0 \quad \text{on } \partial \Omega_F, \quad \operatorname{Re} \lambda_j \geq -\alpha,
\end{aligned} \tag{8}$$

and if in addition (ϕ_j, ψ_j) satisfies

$$\int_{\partial \Omega_F} g_i \cdot \sigma(\phi_j, \psi_j) n = 0 \quad \text{for all } 1 \leq i \leq N_c,$$

then $\phi_j = 0$ and $\psi_j = 0$. By using a unique continuation theorem due to Fabre and Lebeau (1996), we can explicitly determine the functions g_i so that this condition is satisfied; see Raymond and Thevenet (2010). For feedback stabilization results of the Navier-Stokes equations in two or three dimensions, we refer to Fursikov (2004), Raymond (2006, 2007), Barbu et al. (2006), Badra (2009), and Vazquez and Krstic (2008).

Controllability to Trajectories of Fluid Flows

If $(\tilde{u}(t), \tilde{p}(t))_{0 \leq t < \infty}$ is a solution to the Navier-Stokes system, the controllability problem to the trajectory $(\tilde{u}(t), \tilde{p}(t))_{0 \leq t < \infty}$, in time $T > 0$, may be rewritten as a null controllability problem satisfied by $(v, q) = (u - \tilde{u}, p - \tilde{p})$. The local null controllability in time $T > 0$ follows from the null controllability of the linearized system and from a fixed point argument. The linearized controlled system is

$$\begin{aligned}
& \frac{\partial v}{\partial t} - \nu \Delta v + (\tilde{u}(t) \cdot \nabla) v \\
& + (v \cdot \nabla) \tilde{u}(t) + \nabla q = 0 \\
& \text{and} \quad \operatorname{div} v = 0 \text{ in } \Omega_F \times (0, T), \\
& v = m_c f \quad \text{on } \partial \Omega_F \times (0, T), \\
& v(0) = v_0 \in L^2(\Omega_F; \mathbb{R}^N), \quad \operatorname{div} v_0 = 0.
\end{aligned} \tag{9}$$

The nonnegative function m_c is used to localize the boundary control f . The control f is assumed to satisfy

$$\int_{\partial \Omega_F} m_c f \cdot n = 0. \tag{10}$$

As for general linear dynamical systems, the null controllability of the linearized system follows from an observability inequality for the solutions to the following adjoint system

$$\begin{aligned}
& -\frac{\partial \phi}{\partial t} - \nu \Delta \phi \\
& - (\tilde{u}(t) \cdot \nabla) \phi + (\nabla \tilde{u}(t))^T \phi + \nabla \psi = 0 \\
& \text{and} \quad \operatorname{div} \phi = 0 \text{ in } \Omega_F \times (0, T), \\
& \phi = 0 \quad \text{on } \partial \Omega_F \times (0, T), \\
& \phi(T) \in L^2(\Omega_F; \mathbb{R}^N), \quad \operatorname{div} \phi(T) = 0.
\end{aligned} \tag{11}$$

Contrarily to the stabilization problem, the null controllability by a control of finite dimension seems to be out of reach, and it will be impossible in general. We look for a control $f \in L^2(\partial \Omega_F; \mathbb{R}^N)$, satisfying (10), driving the solution to system (9) in time T to zero, that is, such that the solution $v_{v_0, f}$ obeys $v_{v_0, f}(T) = 0$. The linearized system (9) is null controllable in time $T > 0$ by a boundary control $f \in L^2(\partial \Omega_F; \mathbb{R}^N)$ obeying (10), if and only if there exists $C > 0$ such that

$$\int_{\Omega_F} |\phi(0)|^2 dx \leq C \int_{\partial \Omega_F} m_c |\sigma(\phi, \psi) n|^2 dx, \tag{12}$$

for all solution (ϕ, ψ) of (11). The observability inequality (12) may be proved by establishing weighted energy estimates called “Carleman type estimates”; see Fernandez-Cara et al. (2004) and Fursikov et al. (1996).

Additional Controllability Results for Other Fluid Flow Models

The null controllability of the 2D incompressible Euler equation has been obtained by J.-M. Coron with the so-called “Return Method” (Coron 1996). See also Coron (2007) for additional references (in particular the 3D case has been treated by O. Glass).

Some null controllability results for the one-dimensional compressible Navier-Stokes equations have been obtained in Ervedoza et al. (2012).

Fluid-Structure Models

Fluid-structure models are obtained by coupling an equation describing the evolution of the fluid flow with an equation describing the evolution of the structure. The coupling comes from the balance of momentum and by writing that, at the fluid-structure interface, the fluid velocity is equal to the displacement velocity of the structure.

The most important difficulty in studying those models comes from the fact that the domain occupied by the fluid at time t evolves and depends on the displacement of the structure. In addition, when the structure is deformable, its evolution is usually written in Lagrangian coordinates, while fluid flows are usually described in Eulerian coordinates.

The structure may be a rigid or a deformable body immersed into the fluid. It may also be a deformable structure located at the boundary of the domain occupied by the fluid.

A Rigid Body Immersed in a Three-Dimensional Incompressible Viscous Fluid

In the case of a 3D rigid body $\Omega_S(t)$ immersed in a fluid flow occupying the domain $\Omega_F(t)$, the motion of the rigid body may be described by the position $h(t) \in \mathbb{R}^3$ of its center of mass and by a matrix of rotation $Q(t) \in \mathbb{R}^{3 \times 3}$. The domain $\Omega_S(t)$ and the flow X_S associated with the motion of the structure obey

$$\begin{aligned} X_S(y, t) &= h(t) + Q(t)Q_0^{-1}(y - h(0)), \\ \text{for } y \in \Omega_S(0) &= \Omega_S, \\ \Omega_S(t) &= X_S(\Omega_S(0), t), \end{aligned} \quad (13)$$

and the matrix $Q(t)$ is related to the angular velocity $\omega : (0, T) \mapsto \mathbb{R}^3$, by the differential equation

$$Q'(t) = \omega(t) \times Q(t), \quad Q(0) = Q_0. \quad (14)$$

We consider the case when the fluid flow satisfies the incompressible Navier-Stokes system

(3) in the domain $\Omega_F(t)$ corresponding to Fig. 1. Denoting by $J(t) \in \mathbb{R}^{3 \times 3}$ the tensor of inertia at time t , and by m the mass of the rigid body, the equations of the structure are obtained by writing the balance of linear and angular momenta

$$\begin{aligned} mh'' &= \int_{\partial\Omega_S(t)} \sigma(u, p)ndx, \\ J\omega' &= J\omega \times \omega + \int_{\partial\Omega_S(t)} (x - h) \times \sigma(u, p)ndx, \\ h(0) &= h_0, \quad h'(0) = h_1, \quad \omega(0) = \omega_0, \end{aligned} \quad (15)$$

where n is the normal to $\partial\Omega_S(t)$ outward $\Omega_F(t)$. The system (3)–(13)–(14)–(15) has to be completed with boundary conditions. At the fluid structure interface, the fluid velocity is equal to the displacement velocity of the rigid solid:

$$u(x, t) = h'(t) + \omega(t) \times (x - h(t)), \quad (16)$$

for all $x \in \partial\Omega_S(t)$, $t > 0$. The exterior boundary of the fluid domain is assumed to be fixed $\Gamma_e = \partial\Omega_F(t) \setminus \partial\Omega_S(t)$. The boundary condition on $\Gamma_e \times (0, T)$ may be of the form

$$u = m_c f \quad \text{on } \Gamma_e \times (0, \infty), \quad (17)$$

with $\int_{\Gamma_e} m_c f \cdot n = 0$, f is a control and m_c a localization function.

An Elastic Beam Located at the Boundary of a Two-Dimensional Domain Filled by an Incompressible Viscous Fluid

When the structure is described by an infinite-dimensional model (a partial differential equation or a system of p.d.e.), there are a few existence results for such systems and mainly existence of weak solutions (Chambolle et al. 2005). But for stabilization and control problems of nonlinear systems, we are usually interested in strong solutions. Let us describe a two-dimensional model in which a one-dimensional structure is located on a flat part $\Gamma_S = (0, L) \times \{y_0\}$ of the boundary of the reference configuration of the fluid domain Ω_F . We assume that the structure is an Euler-

Control of Fluid Flows and Fluid-Structure Models, Fig. 1 Reference and deformed configurations

Bernoulli beam with or without damping. The displacement η of the structure in the direction normal to the boundary Γ_S is described by the partial differential equation

$$\begin{aligned} \eta_{tt} - b\eta_{xx} - c\eta_{txx} + a\eta_{xxxx} &= F, \\ \text{in } \Gamma_S \times (0, \infty), \\ \eta &= 0 \quad \text{and} \quad \eta_x = 0 \quad \text{on } \partial\Gamma_S \times (0, \infty), \\ \eta(0) &= \eta_1^0 \quad \text{and} \quad \eta_t(0) = \eta_2^0 \quad \text{in } \Gamma_S, \end{aligned} \quad (18)$$

where η_x , η_{xx} , and η_{xxxx} stand for the first, the second and the fourth derivative of η with respect to $x \in \Gamma_S$. The other derivatives are defined in a similar way. The coefficients b and c are nonnegative, and $a > 0$. The term $c\eta_{txx}$ is a structural damping term. At time t , the structure occupies the position $\Gamma_S(t) = \{(x, y) \mid x \in (0, L), y = y_0 + \eta(x, t)\}$. When Ω_F is a two-dimensional model, Γ_S is of dimension one, and $\partial\Gamma_S$ is reduced to the two extremities of Γ_S . The momentum balance is obtained by writing that F in (18) is given by $F = -\sqrt{1 + \eta_x^2} \sigma(u, p) \tilde{n} \cdot n$, where $\tilde{n}(x, y)$ is the unit normal at $(x, y) \in \Gamma_S(t)$ to $\Gamma_S(t)$ outward $\Omega_F(t)$, and n is the unit normal to Γ_S outward $\Omega_F(0) = \Omega_F$. If in addition, a control f acts as a distributed control in the beam equation, we shall have

$$F = -\sqrt{1 + \eta_x^2} \sigma(u, p) \tilde{n} \cdot n + f. \quad (19)$$

The equality of velocities on $\Gamma_S(t)$ reads as

$$\begin{aligned} u(x, y_0 + \eta(x, t)) &= (0, \eta_t(x, t)), \\ x &\in (0, L), \quad t > 0. \end{aligned} \quad (20)$$

Control of Fluid-Structure Models

To control or to stabilize fluid-structure models, the control may act either in the fluid equation or in the structure equation or in both equations. There are a very few controllability and stabilization results for systems coupling the incompressible Navier-Stokes system with a structure equation. We state below two of those results. Some other results are obtained for simplified one-dimensional models coupling the viscous Burgers equation with the motion of a mass; see Badra and Takahashi (2013) and the references therein.

We have also to mention here recent papers on control problems for systems coupling quasi-stationary Stokes equations with the motion of deformable bodies, modeling micro-organism swimmers at low Reynolds number; see Alouges et al. (2008).

Null Controllability of the Navier-Stokes System Coupled with the Motion of a Rigid Body

The system coupling the incompressible Navier-Stokes system (3) in the domain drawn in Fig. 1, with the motion of a rigid body described by (13)–(14)–(15)–(16), with the boundary control (17), is null controllable locally in a neighborhood of 0. Before linearizing the system in a neighborhood of 0, the fluid equations have to be rewritten in Lagrangian coordinates, that is, in the cylindrical domain $\Omega_F \times (0, \infty)$. The linearized system is the Stokes system coupled with a system of ordinary differential equations. The proof of this null controllability result relies on a Carleman estimate for the adjoint system, see, e.g., Boulakia and Guerrero (2013).

Control of Fluid Flows and Fluid-Structure Models,
Fig. 2 Channel flow with an elastic wall

Feedback Stabilization of the Navier-Stokes System Coupled with a Beam Equation

The system coupling the incompressible Navier-Stokes system (3) in the domain drawn in Fig. 2, with a beam equation (18)–(19)–(20) can be locally stabilized with any prescribed exponential decay rate $-\alpha < 0$, by a feedback control f acting in (18) via (19); see Raymond (2010). The proof consists in showing that the infinitesimal generator of the linearized model is an analytic semigroup (when $c > 0$), that its resolvent is compact, and that the Hautus criterion is satisfied.

When the control acts in the fluid equation, the system coupling (3) in the domain drawn in Fig. 2, with the beam equation (18)–(19)–(20) can be stabilized when $c > 0$. To the best of our knowledge, there is no null controllability result for such systems, even with controls acting both in the structure and fluid equations. The case where the beam equation is approximated by a finite-dimensional model is studied in Lequeurre (2013).

Keywords

Advanced heart failure · Heart transplantation · Left ventricle · LVAD physiological controller · Rotary blood pump · Automatic pump speed controller

Abstract

Heart failure is a disease that happens when the heart cannot pump enough oxygenated blood into the circulatory system to support other organs in the body. A left ventricular assist device (or LVAD) is a mechanical pump that may be implanted in patients who suffer from advanced heart failure to assist their heart in its pumping function. The pump is connected from the left ventricle to the aorta and forms a parallel path of blood flow into the circulatory system. The latest generation of these devices consists of rotary pumps, which are generally much smaller, lighter, and quieter than the first-generation pulsatile-type pumps. The LVAD is controlled by varying the pump rotor speed to adjust the amount of blood flow contributed by the device. If the patient is in a healthcare facility, the rotor speed can be adjusted manually by a trained clinician. An important limitation facing the increased use of these devices is the desire to allow the patient to return home and resume a normal lifestyle. This limitation may be overcome if a physiological controller can be developed to automatically adjust the pump speed based on the patient's need for blood flow. Although several possible experimental controllers have recently been developed and tested in laboratory settings, the current practice remains limited to the pump speed being adjusted by the physician and fixed at a constant setting before allowing the patient to leave the healthcare facility. The development of a physiological controller for the continuous flow rotary LVAD remains an important challenge that has occupied LVAD researchers and engineers for the past several decades.

Introduction

According to the latest statistics, more than 5.7 million adults in the United States suffer from heart failure, and more than 650,000 new cases of heart failure are diagnosed every year (Mozzafarian et al. 2016). This disease remains the number one killer of Americans every year, in spite of remarkable progress in medical therapies over the past several decades. Heart failure occurs when the heart muscle becomes unable to generate the necessary force to push enough oxygenated blood from the left ventricle through the aortic valve into the circulatory system (Fig. 1). In its initial stages, the disease is often managed through lifestyle changes and medications (Yancy et al. 2013). However, as the disease progresses, more advanced treatments become necessary. The continuous flow left ventricular assist device (LVAD), sometimes also referred to as an implantable rotary blood pump (IRBP), is an option for treating patients with advanced heart failure disease.

The LVAD is a mechanical pump whose function is to assist the heart in pumping blood. It consists of an inflow cannula, the pump, an outflow cannula, a controller, and a battery pack (Fig. 2). The latest generation of these devices (For example the HeartMate 3, the HeartWare, and the Jarvik 2000) consists of rotary pumps, which are generally much smaller, lighter, and quieter than the first-generation pulsatile-type pumps (Prinzing et al. 2016). The pump is surgically implanted into the patient's chest with the inflow cannula attached to the left ventricle and the outlet cannula inserted into the ascending aorta. Control of the pump speed is performed by the controller unit which is a small box located outside the patient's body. The LVAD is powered by the batteries connected to the controller unit. Blood flows from the left ventricle through the

Control of Left Ventricular Assist Devices, Fig. 1 (Left) Cross section of the heart. <https://en.wikipedia.org/wiki/Heart>. (Right) Healthy heart and heart failure.

https://www.cdc.gov/dhbsp/data_statistics/fact_sheets/fs_heart_failure.htm

pump to the aorta forming a parallel path to the natural flow from the left ventricle to the aorta through the aortic valve. The LVAD is controlled by varying the pump's rotational speed to adjust the amount of blood flow through the device. Some LVADs are capable of producing blood flow of up to 10 L/min, which can provide complete circulatory support. In normal LVAD operation, however, the heart and LVAD work together cooperatively, providing the amount of blood needed by the body based on the patient's activity level, as well as his/her physiological and emotional conditions. The heart provides blood during every heartbeat by pumping from the left

ventricle through the aortic valve into the circulatory system, while the LVAD provides blood continuously from the left ventricle through the pump into the aorta and the circulatory system.

Heart transplantation is a viable option of care for heart failure patients who fail to respond to lifestyle changes and medication. At any given time, around 3,500 to 4,000 patients in the United States are waiting for a heart transplant, and many will die before receiving a heart. The wait time for a heart transplantation can be several months and often exceeds 300 days on the average. The LVAD is typically used as a bridge to transplantation for patients on the transplant

waiting list. Its main role is to support, or even in some cases substitute, the function of the natural heart while the patient is waiting for a donor heart (Poirier 1997; Frazier and Myers 1999; Olsen 2000). As a last resort for patients with refractory heart failure who are not eligible for heart transplantation, the LVAD can be implanted permanently as a destination therapy. In recent years, studies have also shown that for a very small subset of patients, the LVAD is able to restore the muscles of the failing heart, eliminating the need for a transplant (Simon et al. 2005;

Jakovljevic et al. 2017). An increasing number of these bridge-to-recovery patients will have their LVADs successfully explanted following sufficient recovery of the heart's ability to pump on its own.

The Left Ventricle and Systemic Circulation Model

The heart pumps blood through two different circulation paths as illustrated in Fig. 3 . The left

Control of Left Ventricular Assist Devices,
Fig. 3 Diagram of the systemic and pulmonary
 circulatory systems (Silverthorn 2000)

ventricle pumps oxygen-rich blood to the rest of the body through the systemic circulation path, and the right ventricle pumps oxygen-depleted blood to the lungs through the pulmonary circulation path (Marieb 1994). Due to the different nature of the two circulation paths, each side of the heart has a different workload. The systemic circulation is much longer than the pulmonary one and encounters considerable more resistance. To handle the longer path, the left ventricle is more elastic than the right ventricle, giving it

the strength to pump blood at a higher pressure (Marieb 1994).

The ability of the left ventricle to pump blood is expressed in terms of its elastance function $E(t)$. The elastance function is periodic of period $t_c = 60/HR$ where HR is the heart rate in beats per minute (bpm). During each cardiac cycle t_c , $E(t)$ relates the left ventricular pressure $LVP(t)$ to the left ventricular volume $LVV(t)$ according to the expression (Suga and Sagawa 1974):

$$E(t) = \frac{LVP(t)}{LVV(t) - V_0} \quad (1)$$

where V_0 is a reference volume which corresponds to the theoretical volume in the ventricle at zero pressure. Several mathematical expressions have been derived to model the elastance of a healthy heart over one cardiac cycle. In this article, we use the standard expression (Stergiopoulos et al. 1996):

$$E(t) = (E_{\max} - E_{\min})E_n(t_n) + E_{\min} \quad (2)$$

where $E_n(t_n)$ is the so-called double hill function represented by the expression:

$$E_n(t_n) = 1.55 * \left[\frac{\left(\frac{t_n}{0.7}\right)^{1.9}}{1 + \left(\frac{t_n}{0.7}\right)^{1.9}} \right] * \left[\frac{1}{1 + \left(\frac{t_n}{1.17}\right)^{21.9}} \right] \quad (3)$$

In the above expression, $E_n(t_n)$ is the normalized elastance and $t_n = t/(0.2 + 0.15t_c)$. The constants $E_{\max}$ and $E_{\min}$ in (2) are related to the end-systolic pressure-volume relationship (ESPVR) and the end-diastolic pressure-volume relationship (EDPVR), respectively. Figure 4 shows a plot of $E(t)$ for a healthy heart with $E_{\max} = 2$ mmHg/ml, $E_{\min} = 0.06$ mmHg/ml, and a heart rate of 60 bpm (cardiac cycle $t_c = 1$ s). For a patient with heart failure disease, the elastance expression (2) is modified according to $E_\delta(t) = \delta E(t)$ where δ is a factor such that $0 < \delta \leq 1$ and is used to represent the degree of heart failure. The value of $\delta = 1$ represents a healthy ventricle, and the smaller the value of δ , the more severe is the disease. A correlation between $E_{\max}$ and the degrees of heart failure, as defined according to the New York Heart Association

(NYHA) classification, is noted in Table 1 (Levin et al. 1994).

The heart and its circulation paths are a very complex system that is very difficult to model mathematically. Numerous models of varying degrees of complexity have been developed over the past 25 years or so. An eighth-order hybrid model of the heart, which subdivides the human circulatory system into a number of lumped parameter blocks that include the pulmonary arterial and venous systems as well as both ventricles, has been developed in Giridharan et al. (2002). A different eleventh-order model which includes the resistance of peripheral blood vessels has been developed in Wu et al. (2007). Our interest in this article is a dynamic state-space-type model of the systemic circulation system supported by a rotary LVAD. The model

should be comprehensive enough to capture the important relationships that characterize the patient’s hemodynamic variables and LVAD blood flow while at the same time simple enough to be mathematically tractable and useful for control and optimization purposes. A fifth-order lumped parameter, time-varying, nonlinear state-space dynamic model for the left ventricle supported by a first-order generic continuous flow rotary LVAD, has been developed and validated in Simaan et al. (2009). The model consists of five state variables describing the hemodynamics of the left ventricle and one state variable describing the blood flow through the LVAD. The six state variables in the model are summarized in Table 2, and their relationships over one cardiac cycle are governed by the time-varying nonlinear matrix differential equation (Simaan et al. 2009):

$$\begin{aligned}
\begin{bmatrix} \frac{dx_1}{dt} \\ \frac{dx_2}{dt} \\ \frac{dx_3}{dt} \\ \frac{dx_4}{dt} \\ \frac{dx_5}{dt} \\ \frac{dx_6}{dt} \end{bmatrix} &= \begin{bmatrix} \frac{1}{E(t)} \frac{dE(t)}{dt} & 0 & 0 & 0 & 0 & -E(t) \\ 0 & \frac{-1}{R_S C_R} & \frac{1}{R_S C_R} & 0 & 0 & 0 \\ 0 & \frac{1}{R_S C_R} & \frac{-1}{R_S C_R} & 0 & \frac{1}{C_S} & 0 \\ 0 & 0 & 0 & 0 & \frac{-1}{C_A} & \frac{1}{C_A} \\ 0 & 0 & \frac{-1}{L_S} & \frac{1}{L_S} & \frac{-R_C}{L_S} & 0 \\ \frac{1}{L^*} & 0 & 0 & \frac{-1}{L^*} & 0 & \frac{-R^*}{L^*} \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \\ x_3 \\ x_4 \\ x_5 \\ x_6 \end{bmatrix} \\
&+ \begin{bmatrix} E(t) - E(t) \\ \frac{-1}{C_R} & 0 \\ 0 & 0 \\ 0 & \frac{-1}{C_A} \\ 0 & 0 \\ 0 & 0 \end{bmatrix} \begin{bmatrix} \frac{1}{R_M} r(x_2 - x_1) \\ \frac{1}{R_A} r(x_1 - x_4) \end{bmatrix} + \begin{bmatrix} 0 \\ 0 \\ 0 \\ 0 \\ 0 \\ \frac{-\beta}{L^*} \end{bmatrix} u(t) \quad (4)
\end{aligned}$$

In the above expression, the control variable is $u(t) = \omega^2(t)$ where $\omega(t)$ is the rotational speed of the LVAD in RPM. The entries in the various matrices are the model parameters described in Table 3. The first five rows of (4) are parameters associated with the left ventricle, and in the 6th row are parameters associated with the LVAD. The terms R^* and L^* in the 6th row represent the total resistance and total inductance of the LVAD system (pump + cannulas):

$$R^* = R_i + R_P + R_o + R_{su} \quad (5a)$$

$$L^* = L_i + L_P + L_o \quad (5b)$$

The nonlinear time-varying resistance R_{su} in (5a) is included in the model to characterize a phenomenon called suction. It has the form:

$$R_{su} = \begin{cases} 0 & \text{if } x_1(t) > \bar{x}_1 \\ \alpha(x_1(t) - \bar{x}_1) & \text{if } x_1(t) \leq \bar{x}_1 \end{cases} \quad (6)$$

R_{su} is zero when the pump is operating at normal speeds and is activated when $LVP(t)$ (i.e., state variable $x_1(t)$) becomes less than a pre-determined small threshold $\bar{x}_1$, a condition that occurs at high pump speeds. The value of R_{su} when activated increases linearly as a function of the difference between $x_1(t)$ and $\bar{x}_1$. This increase in R_{su} represents a phenomenon called *ventricular suction* which occurs when the pump is attempting to draw more blood from the ventricle than available. The parameter α in (6) is a cannula-dependent scaling factor. In the model, the values used for the suction parameters are $\alpha = -3.5$ s/ml and $\bar{x}_1 = 1$ mmHg.

The term $r(x)$ in (4) represents the ramp function:

$$r(x) = \begin{cases} x & \text{if } x \geq 0 \\ 0 & \text{if } x < 0 \end{cases} \quad (7)$$

It is used to model the status of the aortic and mitral valves during each cardiac cycle as summarized in Table 4. Note that the condition $x_2 < x_1$ and $x_1 < x_4$ occurs twice and represents the phase when the ventricle is undergoing isovolumic contraction prior to ejection

Control of Left Ventricular Assist Devices, Table 2 State variables in the cardiovascular-LVAD model

Variables	Name	Physiological meaning (units)
$x_1(t)$	LVP(t)	Left ventricular pressure (mmHg)
$x_2(t)$	LAP(t)	Left atrial pressure (mmHg)
$x_3(t)$	AP(t)	Arterial pressure (mmHg)
$x_4(t)$	AoP(t)	Aortic pressure (mmHg)
$x_5(t)$	$Q_T(t)$	Total flow (ml/s)
$x_6(t)$	$Q_P(t)$	Pump flow (ml/s)

Control of Left Ventricular Assist Devices, Table 3 Parameter values in the cardiovascular-LVAD model (4)

Parameters	Value	Physiological meaning
Resistances (mmHg.s/ml)		
R_S	1.0000	Systemic vascular resistance (SVR)
R_M	0.0050	Mitral valve resistance
R_A	0.0010	Aortic valve resistance
R_C	0.0398	Characteristic resistance
R_i	0.0677	Resistance of LVAD inflow cannula
R_P	0.1707	Resistance of LVAD pump
R_o	0.0677	Resistance of LVAD outflow cannula
R_{su}	Refer to Eq. (6) for value	Suction resistance
Elastance (mmHg/ml)	TIME-VARYING	Left ventricle elastance
$E(t)$	Eq. (2), Fig. 4	
Compliances (ml/mmHg)		
C_R	4.4000	Left atrial compliance
C_S	1.3300	Systemic compliance
C_A	0.0800	Aortic compliance
Inertances (mmHg.s ² /ml)		
L_S	0.0005	Inertance of blood in aorta
L_i	0.0127	Inertance of inflow cannula
L_P	0.0218	Pump inertance
L_o	0.0127	Inertance of outflow cannula
Other pump parameter	$\beta = 9.9025 \cdot 10^{-7} \text{ mmHg}/(\text{rpm})^2$	Pump-dependent constant

Control of Left Ventricular Assist Devices, Table 4 Phases of the left ventricle within the cardiac cycle

Conditions of x_1 , x_2 , and x_4 in (4)		Valves status		Phases of the left ventricle
		Mitral	Aortic	
$x_2 < x_1$	$x_1 < x_4$	Closed	Closed	Isovolumic contraction
$x_2 < x_1$	$x_1 < x_4$	Closed	Open	Ejection
$x_2 < x_1$	$x_1 < x_4$	Closed	Closed	Isovolumic relaxation
$x_2 > x_1$	$x_1 < x_4$	Open	Closed	Filling

and isovolumic relaxation after ejection and prior to filling. Finally, the condition $x_2 > x_1$ and $x_1 > x_4$ is not feasible because it represents both mitral and aortic valves being simultaneously open. The four different phases of operation of the left ventricle over four consecutive time intervals within each cardiac cycle are outlined in Table 4. The overall model (4) over each cardiac cycle therefore consists of three different differential equations consecutively representing the four phases of the cardiac cycle: the filling phase, followed by isovolumic contraction, followed by the ejection phase, and followed again by isovolumic relaxation.

Control of the LVAD

Irrespective of how the LVAD is used, whether as bridge to transplantation, destination therapy, or bridge to recovery, its speed needs to be properly controlled for the safety and comfort of the patient. The total amount of blood pumped by the LVAD into the circulatory system (state variable x_5) depends on the LVAD rotational speed ω , which is directly dependent on the power P_E supplied to the LVAD. The relationship between the LVAD speed ω and power P_E is given by the nonlinear expression (Fargallah et al. 2011; Fargallah and Simaan 2013):

$$\omega = \sqrt{\frac{\gamma P_E}{x_6}} \quad (8)$$

where $\gamma = 7.5688 \times 10^9$ and x_6 is the rate of flow in the LVAD. The higher the power supplied to the LVAD, the higher its speed will be, and the more blood will be pumped into the circulatory system. An important engineering challenge facing the increased use of this device is the development of an appropriate controller that automatically adjusts its rotational speed so that the amount of blood pumped by the LVAD is sufficient to meet the patient's blood needs at all times and as the patient's activity level changes. Patients are typically either sleeping or engaged in some type of activity (walking or exercising) which requires different levels of cardiac support. While the heart may be contributing a part of this support through the aortic valve, the LVAD controller should be able to detect the need for additional support and adjust the pump speed accordingly. Unfortunately, such a controller does not exist at this time. The development of such a controller remains an important challenge that has occupied LVAD researchers for the past several decades. At this point, we know that in addition to being robust and reliable, the controller must ensure that the speed ω remains within two patient-dependent extremes, ω_L and ω_H , at all times:

- (a) At the lower end, if the speed is too low ($\omega < \omega_L$), blood may regurgitate back from the aorta to the left ventricle through the pump resulting in what is known as *backflow*, a condition that causes congestion of the pulmonary circulation.
- (b) At the upper end, if the pump speed is too high ($\omega > \omega_H$), the pump will attempt to draw more blood from the ventricle than available. This may cause collapse of the ventricle resulting in a dangerous phenomenon called *ventricular suction*. The occurrence of ventricular suction must be detected quickly and the pump speed reduced back to the normal range $\omega \in [\omega_L, \omega_H]$ before the heart muscle is permanently

damaged. Several algorithms specifically for detecting ventricular suction have been developed over the past 20 years (Yuhki et al. 1999; Vollkron et al. 2006; Simaan et al. 2009; Wang and Simaan 2013; Wang et al. 2015, and others). Figure 5 shows a plot of an LVAD flow signal measured in an in vivo study (Simaan et al. 2009) in which the LVAD speed is increased linearly until suction is reached. This figure shows the drastic change in the characteristics of the LVAD flow signal before and after the onset of suction.

While avoiding these two extremes, the LVAD controller should be able to adjust the speed continuously to adapt to the daily activities and physiological and emotional changes of the patient. In general, controlling the LVAD speed ω is done by varying the power P_E supplied to the LVAD. Figure 6 shows a plot of ω for values of P_E increasing from low to high values. Three important observations can be derived from this plot. First, as expected the relationship between ω and P_E is highly nonlinear. Second, ω has a superposed oscillatory component that has the same pulsatility as the heart rate (60 bpm in this case) which indicates that the beating of the heart seems to modulate the pump speed around its mean value. This is a very interesting and an extremely important phenomenon that has recently been observed in data obtained through clinical studies of intensive care patients implanted with LVADs (Mason et al. 2008). Third, the amplitude of the oscillatory component in ω decreases as P_E increases up to a point when it becomes close to zero when a breakdown occurs. From this point on, the amplitude increases as the pump power is increased. The value of ω at the breakpoint corresponds to the onset of ventricular suction which represents the high end ω_H of the normal operating range of the LVAD.

The controller's function is to regulate the amount of blood pumped by the LVAD into the circulatory system in order to meet the body's requirements for cardiac output (CO) and mean arterial pressure (MAP) (Olsen 2000; Boston

Control of Left Ventricular Assist Devices, Fig. 5 In vivo LVAD flow data as LVAD pump speed is increased (Obtained from animal implanted with rotary blood pump)

Control of Left Ventricular Assist Devices, Fig. 6 Pump speed signal ω as a function of time derived from a linearly increasing pump power P_E

et al. 2003; Shima et al. 1992; Marieb 1994). The eventual goal of the LVAD controller is to enable the patient to leave the healthcare facility and return home to a normal lifestyle. The development of an LVAD controller that is capable of accomplishing this goal is a very difficult problem that has challenged the LVAD research community for more than two decades.

The current practice for most eligible patients is to be sent home with an LVAD running at a fixed constant speed, which cannot be changed manually. This “constant speed control” is determined and set by physicians at the time of discharge from the healthcare facility. The rationale is that the LVAD, continuously running at the set speed, together with the native heart will be

able to provide sufficient blood flow for a limited range of patient movements and activities. While this is not optimal, it is the only viable option available at this time. The hope is that in the near future, a physiological feedback controller based on modern optimal control theory can be developed so that sensor measurements of the left ventricle hemodynamic variables can be the main drivers in deciding how the pump speed should be automatically adjusted for optimal operation of the LVAD in meeting the patient's demands of blood flow.

In the meantime, several conceptual physiological controllers have been developed over the past 20 years or so and tested either in a laboratory using a mock circulatory loop or by computer simulation (for a review of these, see Alomari et al. 2013). Some of these were based on noninvasive data such as estimates of the pump flow rate, while others were based on invasive data such as measurements of some hemodynamic variables (state variables x_1 , x_2 , and/or x_6). Unfortunately, until now none of these have been implemented in a clinical environment. Several of these controllers have been tested and compared (Petrou et al. 2018). A selected summary is given below:

1. Inlet-outlet pressure controller: This controller developed by Bullister et al. (2002) consists of a cascaded arrangement in which measured aortic pressure and heart rate are used to define a set point that corresponds to the minimum of the left ventricular diastolic pressure. This set point is then used to control the pump speed based on the measured minimum left ventricular diastolic pressure.
2. Minimum pump flow controller: This feedback controller developed by Simaan et al. (2009) adjusts the pump speed based on the slope of the minimum pump flow signal. The objective of the controller is to increase the speed until the envelope of the minimum pump flow signal reaches an extreme point indicating the onset of suction and then maintain it below that level afterward.
3. Afterload-impedance controller: This controller developed by Moscato et al. (2010) uses the left ventricular pressure signal to calculate a reference mean pump flow. A proportional-integral controller is then used to control the pump speed by matching the pump flow to the reference pump flow.
4. Preload responsive speed controller: This controller developed by Ochsner et al. (2013) uses measurement of the end-diastolic volume to calculate the desired power output of the LVAD which is then used to determine the pump speed.
5. Pump flow and end-diastolic pressure controller: This controller developed by Mansouri et al. (2015) consists of a cascaded control loop that uses the end-diastolic pressure to compute a desired pump flow. A proportional-integral controller is then used to control the pump speed to match the pump flow to the desired pump flow.
6. A suction prevention and physiological control algorithm was developed by Wang et al. (2015). This algorithm uses two gain-scheduled, proportional-integral controllers that maintain a differential pump speed (ΔRPM) above a user-defined threshold to prevent left ventricular suction while maintaining an average reference differential pressure between the left ventricle and aorta to provide physiologic perfusion.

Summary and Future Directions

The rotary left ventricular assist device has become one of the most viable long-term treatment option for patients awaiting heart transplantation and patients with refractory heart failure. More than 22,000 devices have been implanted to date in the United States, and more than 2,500 new implants occur annually (Kirklin et al. 2017). Many of the recipient patients are confined to a healthcare facility, and a small number have been allowed to go home with an LVAD running at a set constant speed. Many more patients could be allowed to go home if a physiological controller for the LVAD speed were available. Without such a controller, many LVAD patients remain confined to a hospital for

months awaiting a donor heart, an option that is extremely costly and may not be necessary.

Several factors need to be overcome before a physiological controller becomes feasible in a clinical setting. The controller must rely on sensor measurements of hemodynamic variables to detect changes in the body's demand for blood flow as the patient's activity level changes and to close the loop by adjusting the LVAD speed accordingly. The controller must be patient-adaptive, robust, and reliable. To this date, implanting additional sensors in the circulatory system is not recommended and is highly undesirable due to the low reliability and high measurement errors of currently available sensors. Another reason is the high possibility of thrombus formation around the sensors. Estimating the hemodynamic variables, on the other hand, has also been unsuccessful so far due to the lack of robustness and accuracy of the estimates.

Ever since the late 1990s, when the LVAD technology evolved from the pulsatile to the rotary type pumps, one of the most important engineering problems that has preoccupied the LVAD research community has been the development of a physiological controller for the rotational speed of the LVAD. It is expected that this same problem will remain a central focus of the LVAD research activity and innovation in the years to come.

Control of Linear Systems with Delays

Wim Michiels

Numerical Analysis and Applied Mathematics Section, KU Leuven, Leuven (Heverlee), Belgium

Abstract

The presence of time delays in dynamical systems may induce complex behavior, and this behavior is not always intuitive. Even if a system's equation is scalar, oscillations may occur. Time delays in control loops are usually associated with degradation of performance and robustness, but, at the same time, there are situations where time delays are used as controller parameters. In the chapter, basis properties of time-delay systems are described, and an overview of delay effects in control systems is presented.

Keywords

Delay differential equations · Delays as controller parameters · Functional differential equation

Introduction

Time delays are important components of many systems from engineering, economics, and the life sciences, due to the fact that the transfer of material, energy, and information is mostly not instantaneous. They appear, for instance, as computation and communication lags, they model transport phenomena and heredity, and they arise as feedback delays in control loops. An overview of applications, ranging from traffic flow control and lasers with phase-conjugate feedback, over (bio)chemical reactors and cancer modeling, to control of communication networks and control via networks, is included in Sipahi et al. (2011).

The aim of this contribution is to describe some fundamental properties of linear control systems subjected to time delays and to outline principles behind analysis and synthesis methods. Throughout the text, the results will be illustrated by means of the scalar system

$$\dot{x}(t) = u(t - \tau), \quad (1)$$

which, controlled with instantaneous state feedback, $u(t) = -kx(t)$, leads to the closed-loop system

$$\dot{x}(t) = -kx(t - \tau). \quad (2)$$

Although this didactic example is extremely simple, we shall see that its dynamics are already very rich and shed a light on delay effects in control loops.

In some works, the analysis of (2) is called the *hot shower problem*, as it can be interpreted as a (over)simplified model for a human adjusting the temperature in a shower: $x(t)$ then denotes the difference between the water temperature and the desired temperature as felt by the person taking the shower, the term $-kx(t)$ models the reaction of the person by further opening or closing taps, and the delay is due to the propagation with finite speed of the water in the ducts.

Basis Properties of Time-Delay Systems

Functional Differential Equation

We focus on a model for a time-delay system described by

$$\dot{x}(t) = A_0x(t) + A_1x(t - \tau), \quad x(t) \in \mathbb{R}^n. \quad (3)$$

This is an example of a *functional differential equation* (FDE) of *retarded type*. The term FDE stems from the property that the right-hand side can be interpreted as a functional evaluated at a piece of trajectory. The term retarded expresses that the right-hand side does not explicitly depend on $\dot{x}$.

As a first difference with an ordinary differential equation, the initial condition of (3) at $t = 0$ is a function ϕ from $[-\tau, 0]$ to $\mathbb{R}^n$. For all $\phi \in \mathcal{C}([-\tau, 0], \mathbb{R}^n)$, where $\mathcal{C}([-\tau, 0], \mathbb{R}^n)$ is the space of continuous functions mapping the interval $[-\tau, 0]$ into $\mathbb{R}^n$, a forward solution $x(\phi)$ exists and is uniquely defined.

In Fig. 1, a solution of the scalar system (2) is shown. The discontinuity in the derivative at $t=0$ stems from $A_0\phi(0) + A_1\phi(-\tau) \neq \lim_{\theta \rightarrow 0} \dot{\phi}$. Due to the smoothing property of an integrator, however, at $t = n\tau$, with $n \in \mathbb{N}$, the discontinuity will only be present in the derivative of order $(n + 1)$. This illustrates a second property of functional differential equations of retarded type: solutions become smoother as time evolves. We note that the presence of discontinuities plays an important role in the development of time-integration methods (Bellen 2013). Finally, as a third major difference with ODEs, backward continuation of solutions is not always possible (Michiels and Niculescu 2014).

Reformulation in a First-Order Form

The state of system (3) at time t is the minimal information needed to continue the solution, which, once again, boils down to a function segment $x_t(\phi)$ where $x_t(\phi)(\theta) = x(\phi)(t + \theta)$, $\theta \in [-\tau, 0]$ (in Fig. 1, the function x_t is shown in red for $t = 5$). This suggests that (3) can be reformulated as a standard ordinary differen-

tial equation over the infinite-dimensional space $\mathcal{C}([-\tau, 0], \mathbb{R}^n)$. This equation takes the form

$$\frac{d}{dt}z(t) = \mathcal{A}z(t), \quad z(t) \in \mathcal{C}([-\tau, 0], \mathbb{R}^n) \quad (4)$$

where operator $\mathcal{A}$ is given by

$$\mathcal{D}(\mathcal{A}) = \left\{ \phi \in \mathcal{C}([-\tau_m, 0], \mathbb{R}^n) : \begin{array}{l} \dot{\phi} \in \mathcal{C}([-\tau_m, 0], \mathbb{R}^n) \\ \dot{\phi}(0) = A_0\phi(0) + A_1\phi(-\tau) \end{array} \right\},$$

$$\mathcal{A}\phi = \frac{d\phi}{d\theta}. \quad (5)$$

The relation between solutions of (3) and (4) is given by $z(t)(\theta) = x(t + \theta)$, $\theta \in [-\tau, 0]$. Note that all system information is concentrated in the nonlocal boundary condition describing the domain of $\mathcal{A}$. The representation (4) is closely related to a description by an advection PDE with a nonlocal boundary condition (Krstic 2009).

Asymptotic Growth Rate of Solutions and Stability

The reformulation of (3) into the standard form (4) allows us to define stability notions and to generalize the stability theory for ordinary differential equations in a straightforward way, with the main change that the state space is $\mathcal{C}([-\tau, 0], \mathbb{R}^n)$. For example, the null solution of (3) is exponentially stable if and only if there

exist constants $C > 0$ and $\gamma > 0$ such that

$$\forall \phi \in \mathcal{C}([-\tau_m, 0], \mathbb{R}^n) \quad \|x_t(\phi)\|_s \leq Ce^{-\gamma t} \|\phi\|_s,$$

where $\|\cdot\|_s$ is the supremum norm and $\|\phi\|_s = \sup_{\theta \in [-\tau, 0]} \|\phi(\theta)\|_2$. Furthermore, asymptotic stability and exponential stability are equivalent. A direct generalization of Lyapunov's second method is described by the following theorem.

Theorem 1 *The null solution of linear system (3) is asymptotically stable if there exist a continuous functional $V : \mathcal{C}([-\tau, 0], \mathbb{R}^n) \rightarrow \mathbb{R}$ (a so-called Lyapunov-Krasovskii functional) and continuous nondecreasing functions $u, v, w : \mathbb{R}^+ \rightarrow \mathbb{R}^+$ with*

$$\begin{aligned} u(0) = v(0) = w(0) = 0 \text{ and } u(s) > 0, \\ v(s) > 0, w(s) > 0 \text{ for } s > 0, \end{aligned}$$

such that for all $\phi \in \mathcal{C}([-\tau, 0], \mathbb{R}^n)$

$$\begin{aligned} u(\|\phi\|_s) \leq V(\phi) \leq v(\|\phi\|_2), \\ \dot{V}(\phi) \leq -w(\|\phi\|_2), \end{aligned}$$

where

$$\dot{V}(\phi) = \limsup_{h \rightarrow 0^+} \frac{1}{h} [V(x_h(\phi)) - V(\phi)].$$

Converse Lyapunov theorems and the construction of the so-called complete-type Lyapunov-Krasovskii functionals are discussed in Kharitonov (2013). Imposing a particular structure on the functional, e.g., a form depending only on a finite number of free parameters, often leads

Control of Linear Systems with Delays, Fig. 1 Solution of (2) for $\tau = 1, k = 1$, and initial condition $\phi \equiv 1$

Control of Linear Systems with Delays, Fig. 2 The classification of stability criteria in delay-independent results and delay-dependent results stems from two differ-

ent perturbation viewpoints. Here, perturbation terms are displayed in *red* color

to easy-to-check stability criteria (for instance, in the form of LMIs), yet as price to pay, the obtained results may be conservative in the sense that the sufficient stability conditions might not be close to necessary conditions. As an alternative to Lyapunov functionals, Lyapunov functions can be used as well, provided that the condition $\dot{V} < 0$ is relaxed (the so-called Lyapunov-Razumikhin approach); see, for example, Gu et al. (2003) and Fridman (2014).

Delay Differential Equations as Perturbation of ODEs

Many results on stability, robust stability, and control of time-delay systems are explicitly or implicitly based on a perturbation point of view, where delay differential equations are seen as perturbations of ordinary differential equations. For instance, in the literature, a classification of stability criteria is often presented in terms of *delay-independent* criteria (conditions holding for all values of the delays) and *delay-dependent* criteria (usually holding for all delays smaller than a bound). This classification has its origin at two different ways of seeing (3) as a perturbation of an ODE, with as nominal system $\dot{x}(t) = A_0 x(t)$ and $\dot{x}(t) = (A_0 + A_1)x(t)$ (system for zero delay), respectively. This observation is

illustrated in Fig. 2 for results based on input-output and Lyapunov-based approaches.

The Spectrum of Linear Time-Delay Systems

Two Eigenvalue Problems

The substitution of an exponential solution in functional differential equation (3) leads us to the *nonlinear eigenvalue problem*

$$(\lambda I - A_0 - A_1 e^{-\lambda\tau})v = 0, \lambda \in \mathbb{C}, v \in \mathbb{C}^n, v \neq 0. \quad (6)$$

The solutions of the equation $\det(\lambda I - A_0 - A_1 e^{-\lambda\tau}) = 0$ are called characteristic roots. Similarly, formulation (4) leads to the equivalent *infinite-dimensional linear eigenvalue problem*

$$(\lambda I - \mathcal{A})u = 0, \lambda \in \mathbb{C}, u \in \mathcal{C}([-\tau, 0], \mathbb{C}^n), u \neq 0. \quad (7)$$

The combination of these two viewpoints lays at the basis of most methods for computing characteristic roots; see Michiels (2012). On the one hand, discretizing (7), i.e., approximating $\mathcal{A}$ with a matrix, and solving the resulting standard eigenvalue problems allow to obtain

global information, for example, estimates of *all* characteristic roots in a given compact set or in a given right half plane. On the other hand, the (finitely many) nonlinear equations (6) allow to make *local corrections* on characteristic root approximations up to the desired accuracy, e.g., using Newton's method or inverse residual iteration. Linear time-delay systems satisfy spectrum-determined growth properties of solutions. For instance, the zero solution of (3) is asymptotically stable if and only if all characteristic roots are in the open left half plane.

In Fig. 3 (left), the rightmost characteristic roots of (2) are depicted for $k\tau = 1$. Note that since the characteristic equation can be written as $\lambda\tau + k\tau e^{-\lambda\tau} = 0$, k and τ can be combined into one parameter. In Fig. 3 (right), we show the real parts of the characteristic roots as a function of $k\tau$. The plots illustrate some important spectral properties of retarded-type FDEs. First, even though there are in general infinitely many characteristic roots, the number of them in *any* right half plane is always finite. Second, the individual characteristic roots, as well as the *spectral abscissa*, i.e., the supremum of the real parts of all characteristic roots, continuously depend on parameters. Related to this, a loss or gain of stability is always associated with characteristic roots crossing the imaginary axis. Figure 3 (right)

also illustrates the transition to a delay-free system as $k\tau \rightarrow 0^+$.

Critical Delays: A Finite-Dimensional Characterization

Assume that for a given value of k , we are looking for values of the delay τ_c for which (2) has a characteristic root $j\omega_c$ on the imaginary axis. From $j\omega = -ke^{-j\omega\tau}$, we get

$$\omega_c = k, \quad \tau_c = \frac{\frac{\pi}{2} + l2\pi}{\omega_c}, \quad l = 0, 1, \dots, \quad \Re \left\{ \frac{d\lambda}{d\tau} \Big|_{(\tau_c, j\omega_c)} \right\}^{-1} = \frac{1}{\omega_c^2}. \quad (8)$$

Critical delay values τ_c are indicated with green circles on Fig. 3 (right). The above formulas first illustrate an *invariance property* of imaginary axis roots and their crossing direction with respect to delay shifts of $2\pi/\omega_c$. Second, the number of possible values of ω_c is one and thus *finite*. More generally, substituting $\lambda = j\omega$ in (6) and treating τ as a free parameter lead to a *two-parameter eigenvalue problem*

$$(j\omega I - A_0 - A_1 z)v = 0, \quad (9)$$

with ω on the real axis and $z := \exp(-j\omega\tau)$ on the unit circle. Most methods to solve such a

Control of Linear Systems with Delays, Fig. 3 (Left) Rightmost characteristic roots of (2) for $k\tau = 1$. (Right) Real parts of rightmost characteristic roots as a function of $k\tau$

problem boil down to an elimination of one of the independent variables ω or z . As an example of an elimination technique, we directly get from (9)

$$\begin{aligned} j\omega \in \sigma(A_0 + A_1 z), \quad -j\omega \in \sigma(A_0^* + A_1^* z^{-1}) \\ \Rightarrow \det\left((A_0 + A_1 z) \oplus (A_0^* + A_1^* z^{-1})\right) = 0, \end{aligned}$$

where $\sigma(\cdot)$ denotes the spectrum and $\oplus$ the Kronecker sum. Clearly, the resulting eigenvalue problem in z is finite dimensional.

Control of Linear Time-Delay System

Limitations Induced by Delays

It is well-known that delays in control loop may lead to a significant degradation of performance and robustness and even to instability (Fridman 2014; Niculescu 2001; Richard 2003). Let us return to example (2). As illustrated with Fig. 3 and expressions (8), the system loses stability if τ reaches the value $\pi/2k$, while stability cannot be recovered for larger delays. The maximum achievable exponential decay rate of the solutions, which corresponds to the minimum of the spectral abscissa, is given by $-1/\tau$; hence, large delays can only be tolerated at the price of a degradation of the rate of convergence. It should be noted that the limitations induced by delays are even more stringent if the uncontrolled systems are exponentially unstable, which is not the case for (2).

The analysis in the previous sections gives a hint why control is difficult in the presence of delays: the system is inherently infinite dimensional. As a consequence, most control design problems which involve determining a finite number of parameters can be interpreted as reduced-order control design problems or as control design problems for under-actuated systems, which both are known to be hard problems.

Fixed-Order Control

Most standard control design techniques lead to controllers whose dimension is larger or equal to the dimension of the system. For infinite-dimensional time-delay system, such

controllers might have a disadvantage of being complicated and hard to implement. To see this, for a system with delay in the state, the generalization of static state feedback, $u(t) = k(x)$, is given by $u(t) = \int_{-\tau}^0 x(t + \theta) d\mu(\theta)$, where μ is a function of bounded variation. However, in the context of large-scale systems, it is known that reduced-order controllers often perform relatively well compared to full-order controllers, while they are much easier to implement.

Recently, methods for the design of controllers with a prescribed order (dimension) or structure have been proposed (Michiels 2012). These methods rely on a direct optimization of appropriately defined cost functions (spectral abscissa, $\mathcal{H}_2/\mathcal{H}_\infty$ criteria). While $\mathcal{H}_2$ criteria can be addressed within a derivative-based optimization framework, $\mathcal{H}_\infty$ criteria and the spectral abscissa require targeted methods for *non-smooth optimization problems*. To illustrate the need for such methods, consider again Fig. 3 (right): minimizing the spectral abscissa for a given value of τ as a function of the controller gain k leads to an optimum where the objective function is not differentiable, even not locally Lipschitz, as shown by the red circle. In case of multiple controller parameters, the path of steepest descent in the parameter space typically has phases along a manifold characterized by the non-differentiability of the objective function.

Using Delays as Controller Parameters

In contrast to the detrimental effects of delays, there are situations where delays have a beneficial effect and are even used as controller parameters; see Sipahi et al. (2011). For instance, delayed feedback can be used to stabilize oscillatory systems where the delay serves to adjust the phase in the control loop. Delayed terms in control laws can also be used to approximate derivatives in the control action. Control laws which depend on the difference $x(t) - x(t - \tau)$, the so-called Pyragas-type feedback, have the property that the position of equilibria and the shape of periodic orbits with period τ are not affected, in contrary to their stability properties. Last but not least, delays can be used in control schemes to generate predictions or to stabilize predictors, which allow

to compensate delays and improve performance (Krstic 2009). Let us illustrate the main idea once more with system (1), considered as model for the shower problem. Its special structure, in the sense that the delay is only present in the input, can be fully exploited.

The person who is taking a shower is – possibly after some bad experiences – aware about the delay and will take into account his/her prediction of the system's reaction when adjusting the cold and hot water supply. Let us formalize this. The uncontrolled system can be rewritten as $\dot{x}(t) = v(t)$, where $v(t) = u(t - \tau)$. We know u up to the current time t ; thus, we know v up to time $t + \tau$, and if $x(t)$ is also known, we can predict the value of x at time $t + \tau$,

$$\begin{aligned} x_p(t + \tau) &= x(t) + \int_t^{t+\tau} v(s) ds \\ &= x(t) + \int_{t-\tau}^t u(s) ds, \end{aligned}$$

and use the predicted state for feedback. With the control law $u(t) = -kx_p(t + \tau)$, there is only one closed-loop characteristic root at $\lambda = -k$, i.e., as long as the model used in the predictor is exact, the delay in the loop is compensated by the prediction. For further reading on prediction-based controllers, see, e.g., Krstic (2009) and the references therein.

Summary and Future Directions

Time-delay systems, which appear in a large number of applications, are a class of infinite-dimensional systems, resulting in rich dynamics and challenges from a control point of view. The different representations and interpretations and, in particular, the combination of viewpoints lead to a wide variety of analysis and synthesis tools.

It is important to mention that many discussed properties do not (necessarily) carry over to functional differential equations of neutral type. In general solutions of neutral type systems do not become smoother as time evolves. Linear time-invariant systems may have infinitely many characteristic roots in a right half plane, while

asymptotic stability does not always imply exponential stability. In the multiple delays case asymptotic stability might even be sensitive with respect to infinitesimal delay perturbations, as discussed in Michiels and Niculescu (2014).

Active research topics include improved structure exploiting methods for robust control, control of complex and networked systems, model reduction approaches for delay systems, as well as applications in traffic, machining and vibration control.

Control of Machining Processes

Kaan Erkorkmaz

Department of Mechanical and Mechatronics Engineering, University of Waterloo, Waterloo, ON, Canada

Abstract

Control of machining processes encompasses a broad range of technologies and innovations, ranging from optimized motion planning and servo drive loop design to on-the-fly regulation of cutting forces and power consumption to applying control strategies for damping out chatter vibrations caused by the interaction of the chip generation mechanism with the machine tool structural dynamics. This article provides a brief introduction to some of the concepts and technologies associated with machining process control.

Keywords

Adaptive control · Chatter vibrations · Feed drive control · Machining · Trajectory planning

Introduction

Machining is used extensively in the manufacturing industry as a shaping process, where high product accuracy, quality, and strength are required. From automotive and aerospace components, to dies and molds, to biomedical implants, and even mobile device chassis,

many manufactured products rely on the use of machining.

Machining is carried out on machine tools, which are multi-axis mechatronic systems designed to provide the relative motion between the tool and workpiece, in order to facilitate the desired cutting operation. Figure 1 illustrates a single axis of a ball screw-driven machine tool, performing a milling operation. Here, the cutting process is influenced by the motion of the servo drive. The faster the part is fed in towards the rotating cutter, the larger the cutting forces become, following a typically proportional relationship that holds for a large class of milling operations (Altintas 2012). The generated cutting forces, in turn, are absorbed by the machine tool and feed drive structure. They cause mechanical deformation and may also excite the vibration modes, if their harmonic content is near the structural natural frequencies. This may, depending on the cutting speed and tool and workpiece engagement conditions, lead to forced vibrations or chatter (Altintas 2012).

The disturbance effect of cutting forces is also felt by the servo control loop, consisting of mechanical, electrical, and digital components. This disturbance may result in the degradation of tool positioning accuracy, thereby leading to part errors. Another input that influences the quality achieved in a machining operation is the commanded trajectory. Discontinuous or poorly designed motion commands, with acceleration discontinuity, lead typically to jerky motion, vibrations, and poor surface finish. Beyond motion controller design and trajectory planning, emerging trends in machining process control include regulating, by feedback, various outcomes of the machining process, such as peak resultant cutting force, spindle power consumption, and amplitude of vibrations caused by the machining process. In addition to using actuators and instrumentation already available on a machine tool, such as feed and spindle drives and current sensors, additional devices, such as dynamometers, accelerometers, as well as inertial or piezoelectric actuators, may need to be used in order to achieve the required level of feedback and control injection capability.

Control of Machining Processes, Fig. 1 Single axis of a ball screw-driven machine tool performing milling

Servo Drive Control

Stringent requirements for part quality, typically specified in microns, coupled with disturbance force inputs coming from the machining process, which can be in the order of tens to thousands of Newtons, require that the disturbance rejection of feed drives, which act as dynamic (i.e., frequency dependent) “stiffness” elements, be kept as strong as possible. In traditional machine design, this is achieved by optimizing the mechanical structure for maximum rigidity. Afterwards, the motion control loop is tuned to yield the highest possible bandwidth (i.e., responsive frequency range), without interfering with the vibratory modes of the machine tool in a way that can cause instability. The P-PI position velocity cascade control structure, shown in Fig. 2, is the most widely used technique in machine tool drives. Its tuning guidelines have been well established in the literature (Ellis 2004). To augment the command following accuracy, velocity and acceleration feedforward, and friction compensation terms are added. Increasing the closed-loop bandwidth yields better disturbance rejection and more accurate

tracking of the commanded trajectory (Pritschow 1996), which is especially important in high-speed machining applications where elevated cutting speeds necessitate faster feed motion.

It can be seen in Fig. 2 that increased axis tracking errors (e_x and e_y) may result in increased contour error (ε). A practical solution to mitigate this problem, in machine tool engineering, is to also match the dynamics of different motion axes, so that the tracking errors always assume an instantaneous proportion that brings the actual tool position as close as possible to the desired toolpath (Koren 1983). Sometimes, the control action can be designed to directly reduce the contour error as well, which leads to the structure known as “cross-coupling control” (Koren 1980).

Trajectory Planning

Smooth trajectory planning with at least acceleration level continuity is required in machine tool control, in order to avoid inducing unwanted vibration or excessive tracking error during the machining process. For this purpose, computer numerical control (CNC) systems are equipped

Control of Machining

Processes, Fig. 2 P-Pi position velocity cascade control used in machine tool drives

**Control of Machining**

Processes, Fig. 3 Formation of contour error (ϵ), as a result of servo errors (e_x and e_y) in the individual axes

with various spline toolpath interpolation functions, such as B-splines, and NURBS. The feedrate (i.e., progression speed along the toolpath) is planned in the “look-ahead” function of the CNC so that the total machining cycle time is reduced as much as possible. This has to be done without violating the position-dependent feedrate limits already programmed into the numerical control (NC) code, which are specified by considering various constraints coming from the machining process.

In feedrate optimization, axis level trajectories have to stay within the velocity and torque limits of the drives, in order to avoid damaging

the machine tool or causing actuator saturation. Moreover, as an indirect way of containing tracking errors, the practice of limiting axis level jerk (i.e., rate of change of acceleration) is applied (Gordon and Erkorkmaz 2013). This results in reduced machining cycle time, while avoiding excessive vibration or positioning error due to “jerky” motion.

An example of trajectory planning using quintic (5th degree) polynomials for toolpath parameterization is shown in Fig. 4. Here, comparison is provided between unoptimized and optimized feedrate profiles subject to the same axis velocity, torque (i.e., control signal), and

Control of Machining Processes, Fig. 4 Example of quintic spline trajectory planning without and with feedrate optimization

jerk limits. As can be seen, significant machining time reduction can be achieved through trajectory optimization, while retaining the dynamic tool position accuracy. While Fig. 4 shows the result of an elaborate nonlinear optimization approach (Altintas and Erkorkmaz 2003), practical look-ahead algorithms have also been proposed which lead to more conservative cycle times but are much better suited for real-time implementation inside a CNC (Weck et al. 1999).

Adaptive Control of Machining

There are established mathematical methods for predicting cutting forces, torque, power, and even surface finish for a variety of machining operations like turning, boring,

drilling, and milling (Altintas 2012). However, when machining complex components, such as gas turbine impellers, or dies and molds, the tool and workpiece engagement and workpiece geometry undergo continuous change. Hence, it may be difficult to apply such prediction models efficiently, unless they are fully integrated inside a computer-aided process planning environment, as reported for 3-axis machining by Altintas and Merdol (2007).

An alternative approach, which allows the machining process to take place within safe and efficient operating bounds, is to use feedback from the machine tool during the cutting process. This measurement can be of the cutting forces using a dynamometer or the spindle power consumption. This measurement is then used inside a feedback control loop

to override the commanded feedrate value, which has direct impact on the cutting forces and power consumption. This scheme can be used to ensure that the cutting forces do not exceed a certain limit for process safety or to increase the feed when the machining capacity is underutilized, thus boosting productivity. Since the geometry and tool engagement are generally continuously varying, the coefficients of a model that relates the cutting force (or power) to the feed command are also time-varying. Furthermore, in CNC controllers, depending on the trajectory generation architecture, the execution latency of a feed override command may not always be deterministic. Due to these sources of variability, rather than using classical fixed gain feedback, machining control research has evolved around adaptive control techniques (Masory and Koren 1980; Spence and Altintas 1991), where changes in the cutting process dynamics are continuously tracked and the control law, which computes the proceeding feedrate override, is updated accordingly. This approach has produced significant cycle time reduction in 5-axis machining of gas turbine impellers, as reported in Budak and Kops (2000) and shown in Fig. 5.

Control of Chatter Vibrations

Chatter vibrations are caused by the interaction of the chip generation mechanism with the

structural dynamics of the machine, tool, and workpiece assembly (see Fig. 6). The relative vibration between the tool and workpiece generates a wavy surface finish. In the consecutive tool pass, a new wave pattern, caused by the current instantaneous vibration, is generated on top of the earlier one. If the formed chip, which has an undulated geometry, displays a steady average thickness, then the resulting cutting forces and vibrations also remain bounded. This leads to a stable steady-state cutting regime, known as “forced vibration.” On the other hand, if the chip thickness keeps increasing at every tool pass, resulting in increased cutting forces and vibrations, then chatter vibration is encountered. Chatter can be extremely detrimental to the machined part quality, tool life, and the machine tool.

Chatter has been reported in literature to be caused by two main phenomena: self-excitation through regeneration and mode coupling. For further information on chatter theory, the reader is referred to Altintas (2012) as an excellent starting point.

Various mitigation measures have been investigated and proposed in order to avoid and control chatter. One widespread approach is to select chatter-free cutting conditions through detailed modal testing and stability analyses. Recently, to achieve higher material removal rates, the application of active damping has started to receive interest. This has been realized through specially designed tools and actuators

Schematic of the chatter vibration mechanism for one degree of freedom (From: Altintas (2012), courtesy of Cambridge University Press)

(Pratt and Nayfeh 2001; Munoa et al. 2013) and demonstrated productivity improvement in boring and milling operations. As another method for chatter suppression, modulation of the cutting (i.e., spindle) speed has been successfully applied as a means of interrupting the regeneration mechanism (Soliman and Ismail 1997; Zatarain et al. 2008).

levels of rigor, so that these new technologies can be utilized reliably and at their full potential.

Summary and Future Directions

This article has presented an overview of various concepts and emerging technologies in the area of machining process control. The new generation of machine tools, designed to meet the ever-growing productivity and efficiency demands, will likely utilize advanced forms of these ideas and technologies in an integrated manner. As more computational power and better sensors become available at lower cost, one can expect to see new features, such as more elaborate trajectory planning algorithms, active vibration damping techniques, and real-time process and machine simulation and control capability, beginning to appear in CNC units. No doubt that the dynamic analysis and controller design for such complicated systems will require higher

Control of Networks of Underwater Vehicles

Naomi Ehrich Leonard
Department of Mechanical and Aerospace
Engineering, Princeton University, Princeton,
NJ, USA

Abstract

Control of networks of underwater vehicles is critical to underwater exploration, mapping, search, and surveillance in the multiscale, spatiotemporal dynamics of oceans, lakes, and rivers. Control methodologies have been derived for tasks including feature

tracking and adaptive sampling and have been successfully demonstrated in the field despite the severe challenges of underwater operations.

Keywords

Adaptive sampling · Feature tracking · Gliders · Mobile sensor arrays · Underwater exploration

Introduction

The development of theory and methodology for control of networks of underwater vehicles is motivated by a multitude of underwater applications and by the unique challenges associated with operating in the oceans, lakes, and rivers. Tasks include underwater exploration, mapping, search, and surveillance, associated with problems that include pollution monitoring, human safety, resource seeking, ocean science, and marine archeology. Vehicle networks collect data on underwater physics, biology, chemistry, and geology for improving the understanding and predictive modeling of natural dynamics and human-influenced changes in marine environments. Because the underwater environment is opaque, inhospitable, uncertain, and dynamic, control is critical to the performance of vehicle networks.

Underwater vehicles typically carry sensors to measure external environmental signals and fields, and thus a vehicle network can be regarded as a mobile sensor array. The underlying principle of control of networks of underwater vehicles leverages their mobility and uses an interacting dynamic among the vehicles to yield a high-performing collective behavior. If the vehicles can communicate their state or measure the relative state of others, then they can cooperate and coordinate their motion.

One of the major drivers of control of underwater mobile sensor networks is the multiscale, spatiotemporal dynamics of the environmental fields and signals. In Curtin et al. (1993), the concept of the autonomous oceanographic sampling network (AOSN),

featuring a network of underwater vehicles, was introduced for dynamic measurement of the ocean environment and resolution of spatial and temporal gradients in the sampled fields. For example, to understand the coupled biological and physical dynamics of the ocean, data are required both on the small-scale dynamics of phytoplankton, which are major actors in the marine ecosystem and the global climate, and on the large-scale dynamics of the flow field, temperature, and salinity.

Accordingly, control laws are needed to coordinate the motion of networks of underwater vehicles to match the many relevant spatial and temporal scales. And for a network of underwater vehicles to perform complex missions reliably and efficiently, the control must address the many uncertainties and real-world constraints including the influence of currents on the motion of the vehicles and the limitations on underwater communication.

Vehicles

Control of networks of underwater vehicles is made possible with the availability of small (e.g., 1.5–2 m long), relatively inexpensive autonomous underwater vehicles (AUVs). Propelled AUVs such as the REMUS provide maneuverability and speed. These kinds of AUVs respond quickly and agilely to the needs of the network, and because of their speed, they can often power through strong ocean flows. However, propelled AUVs are limited by their batteries; for extended missions, they need docking stations or other means to recharge their batteries.

Buoyancy-driven autonomous underwater gliders, including the Slocum, the Spray, and the Seaglider, are a class of endurance AUVs designed explicitly for collecting data over large three-dimensional volumes continuously over periods of weeks or even months (Rudnick et al. 2004). They move slowly and steadily, and, as a result, they are particularly well suited to network missions of long duration.

Gliders propel themselves by alternately increasing and decreasing their buoyancy using either a hydraulic or a mechanical buoyancy engine. Lift generated by flow over fixed wings converts the vertical ascent/descent induced by the change in buoyancy into forward motion, resulting in a sawtooth-like trajectory in the vertical plane. Gliders can actively redistribute internal mass to control attitude, for example, they pitch by sliding their battery pack forward and aft. For heading control, they shift mass to roll, bank, and turn or deflect a rudder. Some gliders are designed for deep water, e.g., to 1,500 m, while others for shallower water, e.g., to 200 m.

Gliders are typically operated at their maximum speed and thus they move at approximately constant speed relative to the flow. Because this is relatively slow, on the order of 0.3–0.5 m/s in the horizontal direction and 0.2 m/s in the vertical, ocean currents can sometimes reach or even exceed the speed of the gliders. Unlike a propelled AUV, which typically has sufficient thrust to maintain course despite currents, a glider trying to move in the direction of a strong current will make no forward progress. This makes coordinated control of gliders challenging; for instance, two sensors that should stay sufficiently far apart may be pushed toward each other leading to less than ideal sampling conditions.

Communication and Sensing

Underwater communication is one of the biggest challenges to the control of networks of underwater vehicles and one that distinguishes it from control of vehicles on land or in the air. Radio-frequency communication is not typically available underwater, and acoustic data telemetry has limitations including sensitivity to ambient noise, unpredictable propagation, limited bandwidth, and latency.

When acoustic communication is too limiting, vehicles can surface periodically and communicate via satellite. This method may be bandwidth limited and will require time and energy. However, in the case of profiling propelled AUVs

or underwater gliders, they already move in the vertical plane in a sawtooth pattern and thus regularly come closer to the surface. When on the surface, vehicles can also get a GPS fix whereas there is no access to GPS underwater. The GPS fix is used for correcting onboard dead reckoning of the vehicle's absolute position and for updating onboard estimation of the underwater currents, both helpful for control.

Vehicles are typically equipped with conductivity-temperature-density (CTD) sensors to measure temperature, salinity, and density. From this pressure can be computed and thus depth and vertical speed. Attitude sensors provide measurements of pitch, roll, and heading. Position and velocity in the plane is estimated using dead reckoning. Many sensors for measuring the environment have been developed for use on underwater vehicles; these include chlorophyll fluorometers to estimate phytoplankton abundance, acoustic Doppler profilers (ADPs) to measure variations in water velocity, and sensors to measure pH, dissolved oxygen, and carbon dioxide.

Control

Described here are a selection of control methodologies designed to serve a variety of underwater applications and to address many of the challenges described above for both propelled AUVs and underwater gliders. Some of these methodologies have been successfully field tested in the ocean.

Formations for Tracking Gradients, Boundaries, and Level Sets in Sampled Fields

While a small underwater vehicle can take only single-point measurements of a field, a network of N vehicles employing cooperative control laws can move as a formation and estimate or track a gradient in the field. This can be done in a straightforward way in 2D with three vehicles and can be extended to 3D with additional vehicles. Consider $N = 3$ vehicles moving together in an equilateral triangular formation and sampling a

2D field $T : \mathbb{R}^2 \rightarrow \mathbb{R}$. The formation serves as a sensor array and the triangle side length defines the resolution of the array.

Let the position of the i th vehicle be $\mathbf{x}_i \in \mathbb{R}^2$. Consider double integrator dynamics $\ddot{\mathbf{x}}_i = \mathbf{u}_i$, where $\mathbf{u}_i \in \mathbb{R}^2$ is the control force on the i th vehicle. Suppose that each vehicle can measure the relative position of each of its neighbors, $\mathbf{x}_{ij} = \mathbf{x}_i - \mathbf{x}_j$. Decentralized control that derives from an artificial potential is a popular method for each of the three vehicles to stay in the triangular formation of prescribed resolution d_0 . Consider the nonlinear interaction potential $V_I : \mathbb{R}^2 \rightarrow \mathbb{R}$ defined as

$$V_I(\mathbf{x}_{ij}) = k_s \left(\ln \|\mathbf{x}_{ij}\| + \frac{d_0}{\|\mathbf{x}_{ij}\|^2} \right)$$

where $k_s > 0$ is a scalar gain. The control law for the i th vehicle derives as the gradient of this potential with respect to $\mathbf{x}_i$ as follows:

$$\ddot{\mathbf{x}}_i = \mathbf{u}_i = - \sum_{j=1, j \neq i}^N \nabla V_I(\mathbf{x}_{ij}) - k_d \dot{\mathbf{x}}_i$$

where a damping term is added with scalar gain $k_d > 0$. Stability of the triangle of resolution d_0 is proved with the Lyapunov function

$$V = \frac{1}{2} \sum_{i=1}^N \|\dot{\mathbf{x}}_i\|^2 + \sum_{i=1}^{N-1} \sum_{j=i+1}^N V_I(\mathbf{x}_{ij}).$$

Now let each vehicle use the sequence of single-point measurements it takes along its path to compute the projection of the spatial gradient onto its normalized velocity, $\mathbf{e}_{\dot{\mathbf{x}}} = \dot{\mathbf{x}}_i / \|\dot{\mathbf{x}}_i\|$, i.e., $\nabla T_P(\mathbf{x}, \dot{\mathbf{x}}_i) = (\nabla T(\mathbf{x}) \cdot \mathbf{e}_{\dot{\mathbf{x}}}) \mathbf{e}_{\dot{\mathbf{x}}}$. Following Bachmayer and Leonard (2002), let

$$\ddot{\mathbf{x}}_i = \mathbf{u}_i = \kappa \nabla T_P(\mathbf{x}, \dot{\mathbf{x}}_i) - \sum_{j=1, j \neq i}^N \nabla V_I(\mathbf{x}_{ij}) - k_d \dot{\mathbf{x}}_i,$$

where κ is a scalar gain. For $\kappa > 0$, each vehicle will accelerate along its path when it measures an increasing T and decelerates for a decreasing T . Each vehicle will also turn to keep up with the

others so that the formation will climb the spatial gradient of T to find a local maximum.

Alternative control strategies have been developed that add versatility in feature tracking. The virtual body and artificial potential (VBAP) multivehicle control methodology (Ögren et al. 2004) was demonstrated with a network of Slocum autonomous underwater gliders in the AOSN II field experiment in Monterey Bay, California, in August 2003 (Fiorelli et al. 2006). VBAP is well suited to the operational scenario described above in which vehicles surface asynchronously to establish communication with a base.

VBAP is a control methodology for coordinating the translation, rotation, and dilation of a group of vehicles. A virtual body is defined by a set of reference points that move according to dynamics that are computed centrally and made available to the vehicles in the group. Artificial potentials are used to couple the dynamics of vehicles and a virtual body so that control laws can be derived that stabilize desired formations of vehicles and a virtual body. When sampled measurements of a scalar field can be communicated, the local gradients can be estimated. Gradient climbing algorithms prescribe virtual body direction, so that, for example, the vehicle network can be directed to head for the coldest water or the highest concentration of phytoplankton. Further, the formation can be dilated so that the resolution can be adapted to minimize error in estimates. Control of the speed of the virtual body ensures stability and convergence of the vehicle formation.

These ideas have been extended further to design provable control laws for cooperative level set tracking, whereby small vehicle groups cooperate to generate contour plots of noisy, unknown fields, adjusting their formation shape to provide optimal filtering of their noisy measurements (Zhang and Leonard 2010).

Motion Patterns for Adaptive Sampling

A central objective in many underwater applications is to design provable and reliable mobile sensor networks for collecting the richest data set in an uncertain environment given limited resources. Consider the sampling of a single

time- and space-varying scalar field, like temperature T , using a network of vehicles, where the control problem is to coordinate the motion of the network to maximize information on this field over a given area or volume.

The definition of the information metric will depend on the application. If the data are to be assimilated into a high-resolution dynamical ocean model, then the metric would be defined by uncertainty as computed by the model. A general-purpose metric, based on objective analysis (linear statistical estimation from given field statistics), specifies the statistical uncertainty of the field model as a function of where and when the data were taken (Bennett 2002). The posteriori error $A(\mathbf{r}, t)$ is the variance of T about its estimate at location $\mathbf{r}$ and time t . Entropic information over a spatial domain of area $\mathcal{A}$ is

$$\mathcal{I}(t) = -\log \left(\frac{1}{\sigma_0 \mathcal{A}} \int d\mathbf{r} A(\mathbf{r}, t) \right),$$

where σ_0 is a scaling factor (Grocholsky 2002).

Computing coordinated trajectories to maximize $\mathcal{I}(t)$ can in principle be addressed using optimal coverage control methods. However, this coverage problem is especially challenging since the uncertainty field is spatially nonuniform and it changes with time and with the motion of the sampling vehicles. Furthermore, the optimal trajectories may become quite complex so that controlling vehicles to them in the presence of dynamic disturbances and uncertainty may lead to suboptimal performance.

An alternative approach decouples the design of motion patterns to optimize the entropic information metric from the decentralized control laws that stabilize the network onto the motion patterns (see Leonard et al. 2007). This approach was demonstrated with a network of 6 Slocum autonomous underwater gliders in a 24-day-long field experiment in Monterey Bay, California, in August 2006 (see Leonard et al. 2010). The coordinating feedback laws for the individual vehicles derive systematically from a control methodology that provides provable stabilization of a parameterized family of collective motion patterns (Sepulchre et al. 2008). These patterns con-

sist of vehicles moving on a finite set of closed curves with spacing between vehicles defined by a small number of “synchrony” parameters. The feedback laws that stabilize a given motion pattern use the same synchrony parameters that distinguish the desired pattern.

Each vehicle moves in response to the relative position and direction of its neighbors so that it keeps moving, it maintains the desired spacing, and it stays close to its assigned curve. It has been observed in the ocean, for vehicles carrying out this coordinated control law, that “when a vehicle on a curve is slowed down by a strong opposing flow field, it will cut inside a curve to make up distance and its neighbor on the same curve will cut outside the curve so that it does not overtake the slower vehicle and compromise the desired spacing” (Leonard et al. 2010). The approach is robust to vehicle failure since there are no leaders in the network, and it is scalable since the control law for each vehicle can be defined in terms of the state of a few other vehicles, independent of the total number of vehicles.

The control methodology prescribes steering laws for vehicles operated at a constant speed. Assume that the i th vehicle moves at unit speed in the plane in the direction $\theta_i(t)$ at time t . Then, the velocity of the i th vehicle is $\dot{\mathbf{x}}_i = (\cos \theta_i, \sin \theta_i)$. The steering control u_i is the component of the force in the direction normal to velocity, such that $\dot{\theta}_i = u_i$ for $i = 1, \dots, N$. Define

$$U(\theta_1, \dots, \theta_N) = \frac{N}{2} \|\mathbf{p}_\theta\|^2, \quad \mathbf{p}_\theta = \frac{1}{N} \sum_{j=1}^N \dot{\mathbf{x}}_j.$$

U is a potential function that is maximal at 1 when all vehicle directions are synchronized and minimal at 0 when all vehicle directions are perfectly anti-synchronized. Let $\tilde{\mathbf{x}}_i = (\tilde{x}_i, \tilde{y}_i) = (1/N) \sum_{j=1}^N \mathbf{x}_{ij}$ and let $\tilde{\mathbf{x}}_i^\perp = (-\tilde{y}_i, \tilde{x}_i)$. Define

$$S(\mathbf{x}_1, \dots, \mathbf{x}_N, \theta_1, \dots, \theta_N) = \frac{1}{2} \sum_{i=1}^N \|\dot{\mathbf{x}}_i - \omega_0 \tilde{\mathbf{x}}_i^\perp\|^2,$$

where $\omega_0 \neq 0$. S is a potential function that is minimal at 0 for circular motion of the vehicles

around their center of mass with radius $\rho_0 = |\omega_0|^{-1}$.

Define the steering control as

$$\dot{\theta}_i = \omega_0(1 + K_c \langle \tilde{\mathbf{x}}_i, \dot{\mathbf{x}}_i \rangle) - K_\theta \sum_{j=1}^N \sin(\theta_j - \theta_i),$$

where $K_c > 0$ and K_θ are scalar gains. Then, circular motion of the network is a steady solution, with the phase-locked heading arrangement a minimum of $K_\theta U$, i.e., synchronized or perfectly anti-synchronized depending on the sign of K_θ . Stability can be proved with the Lyapunov function $V_{c\theta} = K_c S + K_\theta U$. This steering control law depends only on relative position and relative heading measurements of the other vehicles.

The general form of the methodology extends the above control law to network interconnections defined by possibly time-varying graphs with limited sensing or communication links, and it provides systematic control laws to stabilize symmetric patterns of heading distributions about noncircular closed curves. It also allows for multiple graphs to handle multiple scales. For example, in the 2006 field experiment, the default motion pattern was one in which six gliders moved in coordinated pairs around three closed curves; one graph defined the smaller-scale coordination of each pair of gliders about its curve, while a second graph defined the larger-scale coordination of gliders across the three curves.

Implementation

Implementation of control of networks of underwater vehicles requires coping with the remote, hostile underwater environment. The control methodology for motion patterns and adaptive sampling, described above, was implemented in the field using a customized software infrastructure called the Glider Coordinated Control System (GCCS) (Paley et al. 2008). The GCCS combines a simple model for control planning with a detailed model of glider dynamics to accommodate the constant speed of gliders, relatively large ocean currents, waypoint tracking routines, communication only when gliders

surface (asynchronously), other latencies, and more. Other approaches consider control design in the presence of a flow field, formal methods to integrate high-resolution models of the flow field, and design tailored to propelled AUVs.

Summary and Future Directions

The multiscale, spatiotemporal dynamics of the underwater environment drive the need for well-coordinated control of networks of underwater vehicles that can manage the significant operational challenges of the opaque, uncertain, inhospitable, and dynamic oceans, lakes, and rivers. Control theory and algorithms have been developed to enable networks of vehicles to successfully operate as adaptable sensor arrays in missions that include feature tracking and adaptive sampling. Future work will improve control in the presence of strong and unpredictable flow fields and will leverage the latest in battery and underwater communication technologies. Hybrid vehicles and heterogeneous networks of vehicles will also promote advances in control. Future work will draw inspiration from the rapidly growing literature in decentralized cooperative control strategies and complex dynamic networks. Dynamics of decision-making teams of robotic vehicles and humans is yet another important direction of research that will impact the success of control of networks of underwater vehicles.

²Department of Mechanical and Aerospace Engineering, University of California, San Diego, La Jolla, CA, USA

Abstract

The reader is introduced to the predictor feedback method for the control of general nonlinear systems with input delays of arbitrary length. The delays need not necessarily be constant but can be time-varying or state-dependent. The predictor feedback methodology employs a model-based construction of the (unmeasurable) future state of the system. The analysis methodology is based on the concept of infinite-dimensional backstepping transformation – a transformation that converts the overall feedback system to a new, cascade “target system” whose stability can be studied with the construction of a Lyapunov function.

Nonlinear Systems with Input Delay

Nonlinear systems of the form

$$\dot{X}(t) = f(X(t), U(t - D(t, X(t))))), \quad (1)$$

where $t \in \mathbb{R}_+$ is time, $f : \mathbb{R}^n \times \mathbb{R} \rightarrow \mathbb{R}^n$ is a vector field, $X \in \mathbb{R}^n$ is the state, $D : \mathbb{R}_+ \times \mathbb{R}^n \rightarrow \mathbb{R}_+$ is a nonnegative function of the state of the system, and $U \in \mathbb{R}$ is the scalar input, which are ubiquitous in applications.

The starting point for designing a control law for (1), as well as for analyzing the dynamics of (1), is to consider the delay-free counterpart of (1), i.e., when $D = 0$, for which a plethora of results exists dealing with its stabilization and Lyapunov-based analysis (Krstic et al. 1995).

Systems of the form (1) constitute more realistic models for physical systems than delay-free systems. The reason is that often in engineering applications, the control that is applied to the system does not immediately affect the system. This dead time until the controller can affect the system might be due to, among other things, the long distance of the controller from the system, such as in networked control systems, or due to finite-speed transport or flow phenomena, such as in additive manufacturing and cooling systems, or due to various after-effects, such as in population dynamics.

The first step toward control design and analysis for system (1) is to consider the special case in which $D = \text{const}$. The next step is to consider the special case of system (1), in which $D = D(t)$, i.e., the delay is an a priori given function of time. Systems with time-varying delays model numerous real-world systems, such as networked control systems, traffic systems, or irrigation channels. Assuming that the input delay is an a priori defined function of time is a plausible assumption for some applications. Yet, the time variation of the delay might be the result of the variation of a physical quantity that has its own dynamics, such as in milling processes (due to speed variations), 3D printers (due to distance variations), cooling systems (due to flow rate variations), and population dynamics (due to population's size variations). Processes in this category can be modeled by systems with a delay that is a function of the state of the system, i.e., by (1) with $D = D(X)$.

In this article control designs are presented for the stabilization of nonlinear systems with input delays, with delays that are constant (Krstic 2009), time-varying (Bekiaris-Liberis and Krstic 2012), or state-dependent (Bekiaris-Liberis and Krstic 2013b), employing predictor feedback, i.e., employing a feedback law that uses the future rather than the current state of the system. Since

one employs in the feedback law the future values of the state, the predictor feedback completely cancels (compensates) the input delay, i.e., after the control signal reaches the system, the state evolves as if there were no delay at all. Since the future values of the state are not a priori known, the main control challenge is the implementation of the predictor feedback law. Having determined the predictor, the control law is then obtained by replacing the current state in a nominal state-feedback law (which stabilizes the delay-free system) by the predictor.

A methodology is presented in the article for the stability analysis of the closed-loop system under predictor feedback by constructing Lyapunov functionals. The Lyapunov functionals are constructed for a transformed (rather than the original) system. The transformed system is, in turn, constructed by transforming the original actuator state $U(\theta)$, $\theta \in [t - D, t]$ to a transformed actuator state with the aid of an infinite-

dimensional backstepping transformation. The overall transformed system is easier to analyze than the original system because it is a cascade, rather than a feedback system, consisting of a delay line with zero input, whose effect fades away in finite time, namely, after D time units, cascaded with an asymptotically stable system.

Predictor Feedback

The predictor feedback designs are based on a feedback law $U(t) = \kappa(X(t))$ that renders the closed-loop system $\dot{X} = f(X, \kappa(X))$ globally asymptotically stable. For stabilizing system (1), the following control law is employed instead:

$$U(t) = \kappa(P(t)), \quad (2)$$

where

$$P(\theta) = X(t) + \int_{t-D(t, X(t))}^{\theta} \frac{f(P(s), U(s))}{1 - D_t(\sigma(s), P(s)) - \nabla D(\sigma(s), P(s)) f(P(s), U(s))} ds \quad (3)$$

$$\sigma(\theta) = t + \int_{t-D(t, X(t))}^{\theta} \frac{1}{1 - D_t(\sigma(s), P(s)) - \nabla D(\sigma(s), P(s)) f(P(s), U(s))} ds, \quad (4)$$

for all $t - D(t, X(t)) \leq \theta \leq t$. The signal P is the predictor of X at the appropriate prediction time σ , i.e., $P(t) = X(\sigma(t))$. This fact is explained in more detail in the next paragraphs of this section. The predictor employs the future values of the state X which are not a priori available. Therefore, for actually implementing the feedback law (2), one has to employ (3). Relation (3) is a formula for the future values of the state that depends on the available measured quantities, i.e., the current state $X(t)$ and the history of the actuator state $U(\theta)$, $\theta \in [t - D(t, X(t)), t]$. To make clear the definitions of the predictor P and the prediction time σ , as well as their implementation through formulas (3) and (4), the constant delay case is discussed first.

The idea of predictor feedback is to employ in the control law the future values of the state at

the appropriate future time, such that the effect of the input delay is completely canceled (compensated). Define the quantity $\phi(t) = t - D$, which from now on is referred to as the delayed time. This is the time instant at which the control signal that currently affects the system was actually applied. To cancel the effect of this delay, the control law (2) is designed such that $U(\phi(t)) = U(t - D) = \kappa(X(t))$, i.e., such that $U(t) = \kappa(X(\phi^{-1}(t))) = \kappa(X(t + D))$. Define the prediction time σ through the relation $\phi^{-1}(t) = \sigma(t) = t + D$. This is the time instant at which an input signal that is currently applied actually affects the system. In the case of a constant delay, the prediction time is simply D time units in the future. Next an implementable formula for $X(\sigma(t)) = X(t + D)$ is derived. Performing a change of variables $t = \theta + D$, for

all $t - D \leq \theta \leq t$ in $\dot{X}(t) = f(X(t), U(t - D))$ and integrating in θ starting at $\theta = t - D$, one can conclude that P defined by (3) with $D_t = \nabla Df = 0$ and $D = \text{const}$ is the D time units ahead predictor of X , i.e., $P(t) = X(\sigma(t)) = X(t + D)$.

To better understand definition (3), the case of a linear system with a constant input delay D , i.e., a system of the form $\dot{X}(t) = AX(t) + BU(t - D)$, is considered next (see also ► [Control of Linear Systems with Delays](#) and Hale and Lunel 1993). In this case, the predictor $P(t)$ is given explicitly using the variation of constants formula, with the initial condition $P(t - D) = X(t)$, as $P(t) = e^{AD}X(t) + \int_{t-D}^t e^{A(t-\theta)}BU(\theta)d\theta$. For systems that are nonlinear, $P(t)$ cannot be written explicitly, for the same reason that a nonlinear ODE cannot be solved explicitly. So $P(t)$ is represented implicitly using the nonlinear integral equation (3). The computation of $P(t)$ from (3) is straightforward with a discretized implementation in which $P(t)$ is assigned values based on the right-hand side of (3), which involves earlier values of P and the values of the input U .

The case $D = D(t)$ is considered next. As in the case of constant delays, the main goal is to implement the predictor P . One needs first to define the appropriate time interval over which the predictor of the state is needed, which, in the constant delay case, is simply D time units in the future. The control law has to satisfy $U(\phi(t)) = \kappa(X(t))$ or $U(t) = \kappa(X(\sigma(t)))$. Hence, one needs to find an implementable formula for $P(t) = X(\sigma(t))$. In the constant delay case, the prediction horizon over which one needs to compute the predictor can be determined based on the knowledge of the delay time since the prediction horizon and the delay time are both equal to D . This is not anymore true in the time-varying case in which the delayed time is defined as $\phi(t) = t - D(t)$, whereas the prediction time as $\phi^{-1}(t) = \sigma(t) = t + D(\sigma(t))$. Employing a change of variables in $\dot{X}(t) = f(X(t), U(t - D(t)))$ as $t = \sigma(\theta)$, for all $\phi(t) \leq \theta \leq t$, and integrating in θ starting at $\theta = \phi(t)$, one obtains the formula for P given by (3) with $D_t = D'(\sigma(t))$, $\nabla Df = 0$, and $D = D(t)$.

Next the case $D = D(X(t))$ is considered. First one has to determine the predictor, i.e., the signal P such that $P(t) = X(\sigma(t))$, where $\sigma(t) = \phi^{-1}(t)$ and $\phi(t) = t - D(X(t))$. In the case of state-dependent delay, the prediction time $\sigma(t)$ depends on the predictor itself, i.e., the time when the current control reaches the system depends on the value of the state at that time, namely, the following implicit relationship holds $P(t) = X(t + D(P(t)))$ (and $X(t) = P(t - D(X(t)))$). This implicit relation can be solved by proceeding as in the time-varying case, i.e., by performing the change of variables $t = \sigma(\theta)$, for all $t - D(X(t)) \leq \theta \leq t$ in $\dot{X}(t) = f(X(t), U(t - D(X(t))))$, and integrating in θ starting at $\theta = t - D(X(t))$, to obtain the formula (3) for P with $D_t = 0$, $\nabla Df = \nabla D(P(s))f(P(s), U(s))$, and $D = D(X(t))$.

Analogously, one can derive the predictor for the case $D = D(t, X(t))$ with the difference that now the prediction time is not given explicitly in terms of P , but it is defined through an implicit relation, namely, it holds that $\sigma(t) = t + D(\sigma(t), P(t))$. Therefore, for actually computing σ , one has to proceed as in the derivation of P , i.e., to differentiate relation $\sigma(\theta) = \theta + D(\sigma(\theta), P(\theta))$ and then integrate starting at the known value $\sigma(t - D(t, X(t))) = t$. It is important to note that the integral equation (4) is needed in the computation of P only when D depends on both X and t .

Backstepping Transformation and Stability Analysis

The predictor feedback designs are based on a feedback law $\kappa(X)$ that renders the closed-loop system $\dot{X} = f(X, \kappa(X))$ globally asymptotically stable. However, in the rest of the section, it is assumed that the feedback law $\kappa(X)$ renders the closed-loop system $\dot{X} = f(X, \kappa(X) + v)$ input-to-state stable (ISS) with respect to v , i.e., there exists a smooth function $S : \mathbb{R}^n \rightarrow \mathbb{R}_+$ and class $\mathcal{K}_\infty$ functions $\alpha_1, \alpha_2, \alpha_3$, and α_4 such that

$$\begin{aligned} \alpha_3(|X(t)|) &\leq S(X(t)) \\ &\leq \alpha_4(|X(t)|) \end{aligned} \quad (5)$$

$$\begin{aligned} & \frac{\partial S(X(t))}{\partial X} f(X(t), \kappa(X(t)) + v(t)) \\ & \leq -\alpha_1(|X(t)|) + \alpha_2(|v(t)|). \end{aligned} \quad (6)$$

Imposing this stronger assumption enables one to construct a Lyapunov functional for the closed-loop systems (1)–(4) with the aid of the Lyapunov characterization of ISS defined in (5) and (6).

The stability analysis of the closed-loop systems (1)–(4) is explained next. Denote the infinite-dimensional backstepping transformation of the actuator state as

$$\begin{aligned} W(\theta) &= U(\theta) - \kappa(P(\theta)), \\ &\text{for all } t - D(t, X(t)) \leq \theta \leq t, \end{aligned} \quad (7)$$

where $P(\theta)$ is given in terms of $U(\theta)$ from (3). Using the fact that $P(t - D(t, X(t))) = X(t)$, for all $t \geq 0$, one gets from (7) that $U(t - D(t, X(t))) = W(t - D(t, X(t))) + \kappa(X(t))$. With the fact that for all $\theta \geq 0$, $U(\theta) = \kappa(P(\theta))$, one obtains from (7) that $W(\theta) = 0$, for all $\theta \geq 0$. Yet, for all $t \leq D(t, X(t))$, i.e., for all $\theta \leq 0$, $W(\theta)$ might be nonzero due to the effect of the arbitrary initial condition $U(\theta)$, $\theta \in [-D(0, X(0)), 0]$. With the above observations, one can transform system (1) with the aid of transformation (7) to the following target system:

$$\begin{aligned} \dot{X}(t) &= f(X(t), \kappa(X(t)) \\ &\quad + W(t - D(t, X(t)))) \end{aligned} \quad (8)$$

$$\begin{aligned} W(t - D(t, X(t))) &= 0, \\ &\text{for } t - D(t, X(t)) \geq 0. \end{aligned} \quad (9)$$

Using relations (5), (6), and (8), (9), one can construct the following Lyapunov functional for showing asymptotic stability of the target system (8), (9), i.e., for the overall system consisting of the vector $X(t)$ and the transformed infinite-dimensional actuator state $W(\theta)$, $t - D(t, X(t)) \leq \theta \leq t$,

$$V(t) = S(X(t)) + \frac{2}{c} \int_0^{L(t)} \frac{\alpha_2(r)}{r} dr, \quad (10)$$

where $c > 0$ is arbitrary and

$$L(t) = \sup_{t - D(t, X(t)) \leq \theta \leq t} \left| e^{c(\sigma(\theta) - t)} W(\theta) \right|. \quad (11)$$

With the invertibility of the backstepping transformation, one can then show global asymptotic stability of the closed-loop system in the original variables (X, U) . In particular, there exists a class $\mathcal{KL}$ function β such that

$$\begin{aligned} & |X(t)| + \sup_{t - D(t, X(t)) \leq \theta \leq t} |U(\theta)| \\ & \leq \beta \left(|X(0)| + \sup_{-D(0, X(0)) \leq \theta \leq 0} |U(\theta)|, t \right), \\ & \text{for all } t \geq 0. \end{aligned} \quad (12)$$

One of the main obstacles in designing globally stabilizing control laws for nonlinear systems with long input delays is the finite escape phenomenon. The input delay may be so large that the control signal cannot reach the system before its state grows unbounded. Therefore, one has to assume that the system $\dot{X} = f(X, \omega)$ is forward complete, i.e., for every initial condition and every bounded input signal, the corresponding solution is defined for all $t \geq 0$.

With the forward completeness requirement, estimate (12) holds globally for constant but arbitrary large delays. For the case of time-varying delays, estimate (12) holds globally as well but under the following four conditions on the delay:

- C1. $D(t) \geq 0$. This condition guarantees the causality of the system.
- C2. $D(t) < \infty$. This condition guarantees that all inputs applied to the system eventually reach the system.
- C3. $\dot{D}(t) < 1$. This condition guarantees that the system never feels input values that are older than the ones it has already felt, i.e., the input signal's direction never gets reversed. (This condition guarantees the existence of $\sigma = \phi^{-1}$.)

- C4. $\dot{D}(t) > -\infty$ This condition guarantees that the delay cannot disappear instantaneously but only gradually.

In the case of state-dependent delays, the delay depends on time as a result of its dependency on the state. Therefore, predictor feedback guarantees stabilization of the system when the delay satisfies the four conditions C1–C4. Yet, since the delay is a nonnegative function of the state, conditions C2–C4 are satisfied by restricting the initial state X and the initial actuator state. Therefore estimate (12) holds locally.

Recommended Reading

The main control design tool for general systems with input delays of arbitrary length is predictor feedback. The reader is referred to Artstein (1982) for the first systematic treatment of general linear systems with constant input delays. The applicability of predictor feedback was extended in Krstic (2009) to several classes of systems, such as nonlinear systems with constant input delays and linear systems with unknown input delays. Subsequently, predictor feedback was extended to general nonlinear systems with nonconstant input and state delays (Bekiaris-Liberis and Krstic 2013a). The main stability analysis tool for systems employing predictor feedback is backstepping. Backstepping was initially introduced for adaptive control of finite-dimensional nonlinear systems (Krstic et al. 1995). The continuum version of backstepping was originally developed for the boundary control of several classes of PDEs in Krstic and Smyshlyaev (2008).

Control of Optical Tweezers

Murti V. Salapaka
Department of Electrical and Computer
Engineering, University of Minnesota
Twin-Cities, Minneapolis, MN, USA

Abstract

Optical tweezers have revolutionized how matter at the micrometer and nanometer scale can be manipulated and interrogated. In this chapter, operating principles of optical tweezers are presented, with a description of the instrumentation employed. Traditional control approaches and modes are described. Modern control methodologies are motivated, and, engineering objectives framed in the modern model based framework are illustrated via an application to motor-protein interrogation.

Keywords

Optical tweezers · Optical traps · Model based control · Single molecule

Introduction: What Are Optical Tweezers

Optical tweezers use radiation pressure of a highly convergent laser beam to trap micron- and

smaller-sized particles in three-dimensional potential wells. In 1970, Arthur Ashkin showed that momentum of laser beams can be used to accelerate and trap individual particles. In a seminal paper in 1986, Ashkin and his collaborators demonstrated that if a highly convergent laser beam formed by passing the laser through a high-numerical-aperture lens is targeted on a particle of appropriate size and optical characteristics, then the beam instead of pushing the particle away would counterintuitively trap the particle near the focus of the lens. The first optical tweezer was realized. Here a change in the laser direction altered the position of the focus and the trap location pulling the particle along. Ashkin won the Nobel Prize for Physics in 2018 largely due to the impact of optical tweezers in diverse applications including in biology for sorting cells (Zhang and Liu 2008) and in physics for exerting and measuring extremely small forces (Chu et al. 1986). Perhaps the most impact of optical tweezers is in its use in measuring and investigating behavior of single biological molecules such as molecular motors (Fazal and Block 2011). With its femto-Newton force resolution, a spatial resolution of less than a nanometer and temporal resolution with millisecond time scales, it has become possible to study the dynamics of motor proteins, such as myosin, kinesin, and dynein.

A basic modern optical tweezer setup is described by Fig. 1. Here, a trapping laser passes through an acousto-optical deflector (AOD), a polarizing beam splitter (PBS), and other optical elements that direct the laser into a high-numerical objective that focuses the laser onto the sample plane where the particle to be trapped is placed. The trapping laser exits the sample plane passing through the particle and is incident on a photodiode (PD1). Another laser, the detection laser, of considerably lower power travels through a separate PBS, passes through the particle and is incident on another photodiode (PD2). Here the location of the particle determines where the detection laser is incident on the photodiode, PD2, and thus measures the location of the bead (illustrated in Fig. 1b). The photodiode measurements, PD1 and

PD2, are processed by a field-programmable gate array which uses the measurements to determine the control signal actuated by the acousto-optical deflector.

Sensing and Actuation

Sensing: Photodiodes for measuring the position of the trapped particles were employed very early for feedback purposes (see Ashkin and Dziedzic 1977). The bandwidth and resolution afforded by photodiodes with sub-millisecond response and sub-nanometer resolution are more than adequate for most applications and are not a limiting factor in the achievable performance from the optical tweezer setups. One challenge for photodiode-based measurement is the nonlinear nature of the sensed signal. Here the position of the detection laser passing through the particle depends on whether the laser is incident near the center of the particle or near the extremities of the particle; when the particle position is such that the laser is positioned near the center, the measured signal varies linearly with the position of the particle and nonlinearly away from the center (see Fig. 1d). Learning approaches can be employed to improve the range of linear behavior (Aggarwal and Salapaka 2010).

Actuation: In modern optical tweezer setups, the direction of the trapping beam is controlled by electro-optic deflectors (EODs) or acousto-optical deflectors (AODs) with EODs providing better bandwidth with less range of motion than AODs. Both these actuation mechanisms afford bandwidths that are orders higher in relation to the time constants of the dynamics of the particle. Indeed, these devices provide high enough bandwidth whereby it is possible to trap multiple particles simultaneously, by multiplexing the laser. In AODs which are typically more prevalent in use, a diffraction grating is created by propagating waves with frequency in the acoustic range via a crystal. The specific frequency of the acoustic wave employed determines the spacing of the grating which in turn determines how much the trapping laser gets diffracted. Thus by changing the frequency in the radio-frequency range, it is

Control of Optical Tweezers, Fig. 1 Illustration of a modern optical tweezer setup

possible to steer the trapping laser's direction. Here the change in the direction of the trapping laser is completed only when the acoustic wave has traveled through the entire crystal. Other non-idealities are caused by the partial reflection of the waves at the crystal boundaries (Klein and Cook 1967). Other means of altering the trap position is to use piezo-mirrors which have the advantage of large range when compared to AODs and EODs but severely compromised bandwidth.

Models and Identification

The analysis of optical forces exerted on a particle admits two regimes: in the first regime, the particle is much smaller than the wavelength of the light, and in the second regime, the particle is larger than the wavelength. When the particle is in the Rayleigh regime with the particle small, the particle is considered as an electric dipole in an electromagnetic field. If the particle size is much larger than the laser's wavelength (the Mie Regime), ray optics-based analysis is admissible (see Ashkin 1992). In both these regimes, first

principle-based analysis can explain why the particle gets trapped in an optical tweezer. However, in a vast range of applications, the particle size is in the intermediate range where the particle size is comparable to the laser's wavelength; in such cases obtaining models from first principles is hard. For small displacements from the trap center, the laser trap behaves similar to a Hookean spring where the dynamics of the particle in the trap admits the model of an over-damped system described by

$$\beta \dot{x}_b + k_T(x_b - x_T) = \eta + f_{\text{ext}} \quad (1)$$

where x_b is the position of the particle, k_T is the stiffness of the trap, x_T denotes the position of the trapping laser, η is white noise that models thermal noise, and f_{ext} is any other external force acting on the particle. Here the trap position x_T can be controlled using an AOD.

The AOD/actuator dynamics is characterized by a transfer function $A(s)$ whereby

$$\hat{x}_T = A(s)\hat{u}(s), \quad (2)$$

where $u(t)$ is the control signal provided to the actuator. The transfer function $A(s)$ due to the physics of the AOD includes right half plane zeros that impose fundamental limits on performance.

The photodiode-based sensing is modeled as

$$y = x_b + v$$

where v models measurement noise. Taking Laplace transforms we obtain

$$\hat{x}_b = \frac{k_T}{\beta s + k_T} x_T + \underbrace{\frac{1}{\beta s + k_T}}_{G_p(s)} (\eta + f_{\text{ext}}); \quad \hat{x}_T = A(s) \hat{u}(s). \quad (3)$$

Letting $G_p(s) = \frac{1}{\beta s + k_T}$, it follows that $G_h = k_T G_p(s) A(s)$ is the transfer function mapping the control signal u to the bead displacement and x_b , and, G_p is the transfer function from thermal noise η to x_b . By conducting an open-loop experiment, it is possible to identify the transfer function $G_p(s)$ where the response due to the white thermal noise excitation, η , can be employed. Moreover, it is possible to identify G_h using the control signal u as input and x_b as the output response. Using the identified G_h and G_T , it is possible to retrieve $A(s) = \frac{G_h}{k_T G_p}$. As alluded to earlier, $A(s)$ includes right half plane zeros imposing fundamental limitations (Sehgal et al. 2009).

Optical tweezers, apart from being used for manipulating micron-sized particles, provide sensing mechanisms for forces in the femto-Newton to sub-piconewton range as well as sensing motion in the nanometer regime. These operational modes of an optical trap have revolutionized measurement at the small scale, specifically, of single molecules.

Motor proteins such as kinesin and dynein are critical components of intracellular transport. Optical tweezers provide an efficient means of probing motor proteins via bead handles where a polystyrene bead (with radii in the

500 nm – 1 μ m range) is attached to the motor protein and the polystyrene bead is trapped in an optical trap. The optically trapped bead can then be placed on a microtubule; processive motor proteins under the presence of ATP “walk” on the microtubule where the motion of the motor protein can be investigated by monitoring and assessing the forces felt by the trapped bead and its motion (see Fig. 2). Here, often if the motor-protein extension is small, a reasonable model of for the motor protein is that the force it exerts on the bead is $f_{\text{ext}} = -k_m(x_b - x_m)$ where x_m denotes the position of motor protein with $x_b - x_m$ characterizing the extension of the protein and k_m the stiffness of the motor protein. Substituting $f_{\text{ext}} = -k_m(x_b - x_m)$, we obtain

$$\hat{x}_b(s) = k_m G(s) x_m + k_T G(s) x_T + G(s) \eta \quad (4)$$

where $G(s) = \frac{1}{\beta s + k_m + k_T}$.

Traditional Control Paradigms

From the very time of its invention feedback has played a pivotal role in the operation of optical tweezers.

Optical Traps as Force Sensors: Isometric Clamps

Ashkin employed feedback to investigate optical levitation (Ashkin and Dziedzic 1977) where the position of the levitated particle was sensed using a photodiode and a reference position was maintained by altering the laser power (which formed the control signal) to counteract the force that was responsible for the displacement of the particle. The control signal, which is the change in the laser power, provided a measure of the forces on the particle. In Ashkin and Dziedzic (1977) the control signal gave a measure of the electric forces on oil drops thereby measuring single electron change accumulation. The underlying principle adopted is to reject the disturbance force (e.g., due to charge accumulation) that causes the displacement of the particle whereby the control signal rejecting the disturbance becomes

Control of Optical Tweezers, Fig. 2 The figure shows a bead in a trap with the laser focussed at x_T with the bead position, x_b . A motor protein, kinesin, attached to the bead is shown as moving the “cargo” (the bead), along a microtubule placed on a glass coverslip. A high-

resolution method to study motor-protein motion is to optically trap the cargo (the bead) carried by the motor protein while it walks on microtubule. The bead position x_b is changed in response to the change in trap position x_T and the force exerted by the kinesin as it moves

an estimate of the disturbance. The underlying principle is quite powerful; the added benefit is that the displacement is maintained near a desired operating value (the regulated value) wherein a linear analysis and behavior ensue.

In traditional designs the controller employed is $K(s)$ with $\hat{u} = K(s)(\hat{r} - \hat{y})$ where r is the reference position to be regulated. The controllers are primarily proportional or proportional-integral. Traditional practice for designing controllers has not employed models. When estimating external forces, $\hat{f}_{\text{est}} = -k_T u$ is considered as an estimate of f_{ext} . Note that the closed-loop dynamics is described by

$$\begin{aligned}\hat{x}_b &= \frac{k_T G_p A K}{1 + k_T G_p A K} \hat{r} \\ &+ \frac{G_p}{1 + k_T G_p A K} (\hat{\eta} + \hat{f}_{\text{ext}}) \\ &- \frac{k_T G_p A K}{1 + k_T G_p A K} \hat{v},\end{aligned}$$

with

$$\hat{f}_{\text{est}} = -k_T u = -k_T K(\hat{r} - \hat{y}) = k_T K \hat{x}_b,$$

where the position x_b is regulated to zero. Thus the transfer function from f_{ext} to its estimate is

$$\hat{f}_{\text{est}} = \frac{k_T K G_p}{1 + k_T G_p A K} \hat{f}_{\text{ext}}.$$

In traditional schemes for isometric clamps (Finer et al. 1994), the actuator dynamics is ignored (thus $A = 1$) and the assumption that $\frac{k_T K G_p}{1 + k_T G_p A K} \approx 1$ (which holds only at frequencies where the $|(k_T G_p A K)j\omega| \gg 1$) are assumed to hold. The underlying assumptions of the design limit the operation to low-bandwidth operation. Moreover, the behavior due to right hand plane zeros in A manifest in experiments that remained unexplained (see Aggarwal et al. 2011; Sehgal et al. 2009).

Optical Traps as Motion Sensors: Isotonic Clamps

In many applications it is important to regulate a constant force on the system being investigated. The study of motor proteins illustrates the need for regulating a constant force. In the study of motor proteins, a polystyrene bead is attached to the motor protein which traverses the microtubule (see Fig. 2). The bead position x_b increases as it is being pulled along the microtubule, whereby the bead is subjected to increasing forces and the motor protein will come under increasing forces as well. Most single molecules, motor proteins included, are characterized by the wormlike chain model where the stiffness of

the molecule changes with force. Thus the bead position, which is being measured, will provide an inaccurate estimate of the motor motion x_m . Moreover, transport properties of motor proteins are known to be altered when loading conditions change, thus making it difficult to study the effect of load forces on motor-protein behavior. Isotonic clamps regulate $x_b - x_T$ to a desired value e_d (Visscher and Block 1998; Lang et al. 2002) allowing the motor linkage to be modeled as Hookean spring. These methods are not model based and suffer from the similar drawbacks alluded to in relation to isometric clamps. Thus, traditional non-model-based designs (Visscher and Block 1998; Lang et al. 2002) are appropriate for low-bandwidth operation. A modern control approach alleviates challenges with traditional approaches outlined above.

Modern Control Approaches

Modern model-based control approaches allow for controller synthesis that address multiple objectives cast in different measures. Moreover it is possible to regulate variables that are not measured. In what follows, such a modern control approach is illustrated via a design of an isotonic clamp in the study of motor proteins. The main objectives for investigating motor-protein behavior are:

1. The force on the bead in the trap is to be regulated to a set-point F_d . This objective captures the concerns of maintaining the trap dynamics in the linear regime and be able to mirror the regulation goals in traditional schemes. Note that x_b and x_T are available as measured variables. Here, $k_T(x_T - x_b)$ which is the force acting on the bead due to the trap is to be maintained at F_d .
2. The force $k_m(x_m - x_b)$ on the motor protein is to be regulated to a desired value F_m . Note here that x_m is not a measured quantity and thus difficult to directly incorporate this objective in traditional approaches.
3. An accurate estimate x_{em} of the motor position x_m is to be determined.

The exogenous inputs are F_d , F_m , η , and x_m which are the force to be regulated on the bead, force to be regulated on the motor protein, thermal noise, and motor-protein position x_m (Fig. 3).

The regulated variables are weighted error, $z_e = W_e(F_d - k_T(x_b - x_T))$, in regulating forces on the bead, weighted error $z_{em} = W_{em}(F_m - k_m(x_m - x_b))$ in regulating forces on the motor, weighted error in motor motion estimate $z_m = W_m(x_m - x_{em})$, and weighted motor motion estimate $z_n = W_\eta x_{em}$. The weights W_e , W_{em} , W_m , and W_η allow for emphasizing different frequency ranges of relevant objectives they target.

The controller output $\tilde{u}$, apart from providing the actuation input u to the actuator, provides an estimate x_{em} of the motor motion x_m . The controller is described by $\begin{pmatrix} u \\ x_{em} \end{pmatrix} = \begin{pmatrix} K_{11} & K_{12} \\ K_{21} & K_{22} \end{pmatrix} \begin{pmatrix} F_d \\ x_b \end{pmatrix}$. Using the identified models, P_{sys} can be determined. The associated optimization problem to synthesize a controller $K(s)$ is given below :

$$\begin{aligned} \min_{K \text{ stabilizing}, \gamma} \{ & \gamma : \| [T_{z_e f_d} \ T_{z_e x_m}] \|_{H_\infty} < \gamma, \\ & \| [T_{z_{em} x_m}] \|_{H_\infty} < \gamma, \\ & \| T_{z_m x_m} \|_{H_\infty} < \gamma, \\ & \| T_{z_\eta \eta} \|_{H_2}^2 < \nu \} \end{aligned} \quad (5)$$

Here,

$$\begin{aligned} T_{z_e f_d} &= W_e(s)(1 - Gk_T^2 K_{11}(s)A(s)H(s) \\ &\quad + A(s)k_T K_{11}(s)H(s)), \\ T_{z_e x_m} &= W_e(s)k_T G(s)k_m \\ &\quad ((A(s)K_{12}(s) - 1)H(s)), \\ T_{z_{em} x_m} &= W_{em}(s)k_m G(s)k_T A(s)K_{12}(s)H(s), \\ T_{z_m x_m} &= W_m(s)(1 - G(s)k_m K_{22}(s))H(s), \text{ and,} \\ T_{z_\eta \eta} &= W_\eta G(s)K_{22}(s)H(s). \end{aligned} \quad (6)$$

Abstract

Quantum control theory is concerned with the control of systems whose dynamics are governed by the laws of quantum mechanics. Quantum control may take the form of open-loop quantum control or quantum feedback control. Also, quantum feedback control may consist of measurement-based feedback control, in which the controller is a classical system governed by the laws of classical physics. Alternatively, quantum feedback control may take the form of coherent feedback control in which the controller is a quantum system governed by the laws of quantum mechanics. In the area of open-loop quantum control, questions of controllability along with optimal control and Lyapunov control methods are discussed. In the case of quantum feedback control, LQG and H^∞ control methods are discussed.

Introduction

Quantum control is the control of systems whose dynamics are described by the laws of quantum

This work was supported by the Australian Research Council under grants FL11010002 and DP180101805.

physics rather than classical physics. The dynamics of quantum systems must be described using quantum mechanics which allows for uniquely quantum behavior such as entanglement and coherence. There are two main approaches to quantum mechanics which are referred to as the Schrödinger picture and the Heisenberg picture. In the Schrödinger picture, quantum systems are modelled using the Schrödinger equation or a master equation which describe the evolution of the system state or density operator. In the Heisenberg picture, quantum systems are modelled using quantum stochastic differential equations which describe the evolution of system observables. These different approaches to quantum mechanics lead to different approaches to quantum control. Important areas in which quantum control problems arise include physical chemistry, atomic and molecular physics, and optics. Detailed overviews of the field of quantum control can be found in the survey papers Dong and Petersen (2010); Brif et al. (2010) and the monographs Wiseman and Milburn (2010), D'Alessandro (2007), Jacobs (2014), and Nurdin and Yamamoto (2017).

A fundamental problem in a number of approaches to quantum control is the controllability problem. Quantum controllability problems are concerned with finite dimensional quantum systems modelled using the Schrödinger picture of quantum mechanics and involve the structure of corresponding Lie groups or Lie algebras; e.g., see D'Alessandro (2007). These problems are typically concerned with closed quantum systems which are quantum systems isolated from their environment. For a controllable quantum system, an open loop control strategy can be constructed in order to manipulate the quantum state of the system in a general way. Such open loop control strategies are referred to as coherent control strategies. Time-optimal control is one method of constructing these control strategies which has been applied in applications including physical chemistry and in nuclear magnetic resonance systems; e.g., see Khaneja et al. (2001). An alternative approach to open loop quantum control is the Lyapunov approach; e.g., see Wang and Schirmer (2010). This approach extends the

classical Lyapunov control approach in which a control Lyapunov function is used to construct a stabilizing state feedback control law. However in quantum control, state feedback control is not allowed since classical measurements change the quantum state of a system and the Heisenberg uncertainty principle forbids the simultaneous exact classical measurement of non-commuting quantum variables. Also, in many quantum control applications, the timescales are such that real-time classical measurements are not technically feasible. Thus, in order to obtain an open loop control strategy, the deterministic closed loop system is simulated as if the state feedback control were available, and this enables an open loop control strategy to be constructed. As an alternative to coherent open loop control strategies, some classical measurements may be introduced leading to incoherent control strategies; e.g., see Dong et al. (2009).

In addition to open loop quantum control approaches, a number of approaches to quantum control involve the use of feedback; e.g., see Wiseman and Milburn (2010) and Nurdin and Yamamoto (2017). This quantum feedback may either involve the use of classical measurements, in which case the controller is a classical (non-quantum) system, or involve the case where no classical measurements are used since the controller itself is a quantum system. The case in which the controller itself is a quantum system is referred to as coherent quantum feedback control; e.g., see Lloyd (2000) and James et al. (2008). Quantum feedback control may be considered using the Schrödinger picture in which case, the quantum systems under consideration are modelled using stochastic master equations. Alternatively using the Heisenberg picture, the quantum systems under consideration are modelled using quantum stochastic differential equations. Applications in which quantum feedback control can be applied include quantum optics and atomic physics. In addition, quantum control can potentially be applied to problems in quantum information (e.g., see Nielsen and Chuang 2000) such as quantum error correction (e.g., see Kerckhoff et al. 2010) or the preparation of quantum states. Quantum information and

quantum computing in turn have great potential in solving intractable computing problems such as factoring large integers using Shor's algorithm; see Shor (1994).

Schrödinger Picture Models of Quantum Systems

The state of a closed quantum system can be represented by a unit vector $|\psi\rangle$ in a complex Hilbert space $\mathcal{H}$. Such a quantum state is also referred to as a wave function. In the Schrödinger picture, the time evolution of the quantum state is defined by the Schrödinger equation which is in general a partial differential equation. An important class of quantum systems are finite-level systems in which the Hilbert space is finite dimensional. In this case, the Schrödinger equation is a linear ordinary differential equation of the form

$$i\hbar \frac{\partial}{\partial t} |\psi(t)\rangle = H_0 |\psi(t)\rangle$$

where H_0 is the free Hamiltonian of the system, which is a self-adjoint operator on $\mathcal{H}$; e.g., see Merzbacher (1970). Also, $\hbar$ is the reduced Planck's constant, which can be assumed to be one with a suitable choice of units. In the case of a controlled closed quantum system, this differential equation is extended to a bilinear ordinary differential equation of the form

$$i \frac{\partial}{\partial t} |\psi(t)\rangle = \left[H_0 + \sum_{k=1}^m u_k(t) H_k \right] |\psi(t)\rangle \quad (1)$$

where the functions $u_k(t)$ are the control variables and the H_k are corresponding control Hamiltonians, which are also assumed to be self-adjoint operators on the underlying Hilbert space. These models are used in the open loop control of closed quantum systems.

To represent open quantum systems, it is necessary to extend the notion of quantum state to density operators ρ which are positive operators with trace one on the underlying Hilbert space $\mathcal{H}$. In this case, the Schrödinger picture model of a quantum system is given in terms of a master

equation which describes the time evolution of the density operator. In the case of an open quantum system with Markovian dynamics defined on a finite dimensional Hilbert space of dimension N , the master equation is a matrix differential equation of the form

$$\begin{aligned} \dot{\rho}(t) = & -i \left[\left(H_0 + \sum_{k=1}^m u_k(t) H_k \right), \rho(t) \right] \\ & + \frac{1}{2} \sum_{j,k=0}^{N^2-1} \alpha_{j,k} \left([F_j \rho(t), F_k^\dagger] \right. \\ & \left. + [F_j, \rho(t) F_k^\dagger] \right); \end{aligned} \quad (2)$$

e.g., see Breuer and Petruccione (2002). Here the notation $[X, \rho] = X\rho - \rho X$ refers to the commutation operator, and the notation † denotes the adjoint of an operator. Also, $\{F_j\}_{j=0}^{N^2-1}$ is a basis set for the space of bounded linear operators on $\mathcal{H}$ with $F_0 = I$. Also, the matrix $A = (\alpha_{j,k})$ is assumed to be positive definite. These models, which include the Lindblad master equation for dissipative quantum systems as a special case (e.g., see Wiseman and Milburn 2010), are used in the open loop control of finite-level Markovian open quantum systems.

In quantum mechanics, classical measurements are described in terms of self-adjoint operators on the underlying Hilbert space referred to as observables; e.g., see Breuer and Petruccione (2002). An important case of measurements is projective measurements in which an observable M is decomposed as $M = \sum_{k=1}^m k P_k$ where the P_k are orthogonal projection operators on $\mathcal{H}$; e.g., see Nielsen and Chuang (2000). Then, for a closed quantum system with quantum state $|\psi\rangle$, the probability of an outcome k from the measurement is given by $\langle \psi | P_k | \psi \rangle$ which denotes the inner product between the vector $|\psi\rangle$ and the vector $P_k |\psi\rangle$. This notation is referred to as Dirac notation and is commonly used in quantum mechanics. If the outcome of the quantum measurement is k , the state of the quantum system collapses to the new value of $\frac{P_k |\psi\rangle}{\sqrt{\langle \psi | P_k | \psi \rangle}}$. This change in the quantum

state as a result of a measurement is an important characteristic of quantum mechanics. For an open quantum system which is in a quantum state defined by a density operator ρ , the probability of a measurement outcome k is given by $\text{tr}(P_k \rho)$. In this case, the quantum state collapses to $\frac{P_k \rho P_k}{\text{tr}(P_k \rho)}$.

In the case of an open quantum system with continuous measurements of an observable X , we can consider a stochastic master equation as follows:

$$\begin{aligned} d\rho(t) = & -i \left[\left(H_0 + \sum_{k=1}^m u_k(t) H_k \right), \rho(t) \right] dt \\ & -\kappa [X, [X, \rho(t)]] dt \\ & + \sqrt{2\kappa} (X\rho(t) + \rho(t)X) \\ & - 2\text{tr}(X\rho(t)) \rho(t) dW \end{aligned} \quad (3)$$

where κ is a constant parameter related to the measurement strength and dW is a standard Wiener increment which is related to the continuous measurement outcome $y(t)$ by

$$dW = dy - 2\sqrt{\kappa} \text{tr}(X\rho(t)) dt; \quad (4)$$

e.g., see Wiseman and Milburn (2010). These models are used in the measurement feedback control of Markovian open quantum systems. Also, equations (3), (4) can be regarded as a quantum filter in which $\rho(t)$ is the conditional density of the quantum system obtained by filtering the measurement signal $y(t)$; e.g., see Bouten et al. (2007) and Gough et al. (2012).

Heisenberg Picture Models of Quantum Systems

In the Heisenberg picture of quantum mechanics, the observables of a system evolve with time, and the quantum state remains fixed. This picture may also be extended slightly by considering the time evolution of general operators on the underlying Hilbert space rather than just observables which are required to be self-adjoint operators. An important class of open quantum systems which are considered in the Heisenberg

picture arises when the underlying Hilbert space is infinite dimensional, and the system represents a collection of independent quantum harmonic oscillators interacting with a number of external quantum fields. Such linear quantum systems are described in the Heisenberg picture by linear quantum stochastic differential equations (QSDEs) of the form

$$\begin{aligned} dx(t) &= Ax(t)dt + BdW(t); \\ dy(t) &= Cx(t)dt + Dw(t) \end{aligned} \quad (5)$$

where A , B , C , and D are real or complex matrices and $x(t)$ is a vector of possibly non-commuting operators on the underlying Hilbert space $\mathcal{H}$; e.g., see James et al. (2008) and Nurdin and Yamamoto (2017). Also, the quantity $dW(t)$ is decomposed as

$$dW(t) = \beta_w(t)dt + d\tilde{w}(t)$$

where $\beta_w(t)$ is an adapted process and $\tilde{w}(t)$ is a quantum Wiener process with Itô table:

$$d\tilde{w}(t)d\tilde{w}(t)^\dagger = F_w dt.$$

Here, $F_w \geq 0$ is a real or complex matrix. The quantity $w(t)$ represents the components of the input quantum fields acting on the system. Also, the quantity $y(t)$ represents the components of interest of the corresponding output fields that result from the interaction of the harmonic oscillators with the incoming fields.

In order to represent physical quantum systems, the components of vector $x(t)$ are required to satisfy certain commutation relations of the form

$$[x_j(t), x_k(t)] = 2i\Theta_{jk}, \quad j, k = 1, 2, \dots, n, \quad \forall t$$

where the matrix $\Theta = (\Theta_{jk})$ is skew symmetric. The requirement to represent a physical quantum system places restrictions on the matrices A , B , C , and D , which are referred to as physical realizability conditions; e.g., see James et al. (2008) and Shaiju and Petersen (2012). QSDE models of the form (5) arise frequently in the area of

quantum optics. They can also be generalized to allow for nonlinear quantum systems such as arise in the areas of nonlinear quantum optics and superconducting quantum circuits; e.g., see Bertet et al. (2012). These models are used in the feedback control of quantum systems in both the case of classical measurement feedback and in the case of coherent feedback in which the quantum controller is also a quantum system and is represented by such a QSDE model. Some of the properties of linear quantum systems can be described using the quantum Kalman decomposition which was derived in Zhang et al. (2018).

(S, L, H) Quantum System Models

An alternative method of modelling an open quantum system as opposed to the stochastic master equation (SME) approach or the quantum stochastic differential equation (QSDE) approach, which were considered above, is to simply model the quantum system in terms of the physical quantities which underlie the SME and QSDE models. For a general open quantum system, these quantities are the *scattering matrix* S which is a matrix of operators on the underlying Hilbert space, the coupling operator L which is a vector of operators on the underlying Hilbert space, and the system Hamiltonian which is a self-adjoint operator on the underlying Hilbert space; e.g., see Gough and James (2009). For a given (S, L, H) model, the corresponding SME model or QSDE model can be calculated using standard formulas; e.g., see Bouten et al. (2007) and James et al. (2008). Also, in certain circumstances, an (S, L, H) model can be calculated from an SME model or a QSDE model. For example, if the linear QSDE model (5) is physically realizable, then a corresponding (S, L, H) model can be found. In fact, this amounts to the definition of physical realizability.

Open Loop Control of Quantum Systems

A fundamental question in the open loop control of quantum systems is the question of controllability. For the case of a closed quantum system of the form (1), the question of controllability

can be defined as follows (e.g., see Albertini and Alessandro 2003):

Definition 1 (Pure State Controllability) The quantum system (1) is said to be *pure state controllable* if for every pair of initial and final states $|\psi_0\rangle$ and $|\psi_f\rangle$ there exist control functions $\{u_k(t)\}$ and a time $T > 0$ such that the corresponding solution of (1) with initial condition $|\psi_0\rangle$ satisfies $|\psi(T)\rangle = |\psi_f\rangle$.

Alternative definitions have also been considered for the controllability of the quantum system (1); e.g., see Albertini and Alessandro (2003) and Grigoriu et al. (2013) in the case of open quantum systems. The following theorem provides a necessary and sufficient condition for pure state controllability in terms of the Lie algebra $\mathcal{L}_0$ generated by the matrices $\{-iH_0, -iH_1, \dots, -iH_m\}$, $\mathfrak{u}(N)$ the Lie algebra corresponding to the unitary group of dimension N , $\mathfrak{su}(N)$ the Lie algebra corresponding to the special unitary group of dimension N , $\mathfrak{sp}(\frac{N}{2})$ the $\frac{N}{2}$ dimensional symplectic group, and $\tilde{\mathcal{L}}$ the Lie algebra conjugate to $\mathfrak{sp}(\frac{N}{2})$.

Theorem 1 (See D'Alessandro 2007) *The quantum system (1) is pure state controllable if and only if the Lie algebra $\mathcal{L}_0$ satisfies one of the following conditions:*

1. $\mathcal{L}_0 = \mathfrak{su}(N)$;
2. $\mathcal{L}_0$ is conjugate to $\mathfrak{sp}(\frac{N}{2})$;
3. $\mathcal{L}_0 = \mathfrak{u}(N)$;
4. $\mathcal{L}_0 = \text{span}\{iI_{N \times N}\} \oplus \tilde{\mathcal{L}}$.

Similar conditions have been obtained when alternative definitions of controllability are used.

Once it has been determined that a quantum system is controllable, the next task in open loop quantum control is to determine the control functions $\{u_k(t)\}$ which drive a given initial state to a given final state. An important approach to this problem is the optimal control approach in which a time optimal control problem is solved using Pontryagin's maximum principle to construct the control functions $\{u_k(t)\}$ which drives the given initial state to the given final state in minimum time; e.g., see Khaneja et al. (2001). This approach works well for low-dimensional quantum systems but is

computationally intractable for high-dimensional quantum systems.

An alternative approach for high-dimensional quantum systems is the Lyapunov control approach. In this approach, a Lyapunov function is selected which provides a measure of the distance between the current quantum state and the desired terminal quantum state. An example of such a Lyapunov function is

$$V = \langle \psi(t) - \psi_f | \psi(t) - \psi_f \rangle \geq 0;$$

e.g., see Mirrahimi et al. (2005). A state feedback control law is then chosen to ensure that the time derivative of this Lyapunov function is negative. This state feedback control law is then simulated with the quantum system dynamics (1) to give the required open loop control functions $\{u_k(t)\}$.

Classical Measurement-Based Quantum Feedback Control

A Schrödinger Picture Approach to Classical Measurement-Based Quantum Feedback Control

In the Schrödinger picture approach to classical measurement-based quantum feedback control with weak continuous measurements, we begin with the stochastic master equations (3), (4) which are considered as both a model for the system being controlled and as a filter which will form part of the final controller. These filter equations are then combined with a control law of the form

$$u(t) = f(\rho(t))$$

where the function $f(\cdot)$ is designed to achieve a particular objective such as stabilization of the quantum system. Here $u(t)$ represents the vector of control inputs $u_k(t)$. An example of such a quantum control scheme is given in the paper Mirrahimi and van Handel (2007) in which a Lyapunov method is used to design the control law $f(\cdot)$ so that a quantum system consisting of an atomic ensemble interacting with an electromagnetic field is stabilized about a specified state $\rho_f = |\psi_m\rangle\langle\psi_m|$. Here, the notation $|\psi_m\rangle\langle\psi_m|$

refers to the outer product between the vector $|\psi_m\rangle$ and itself.

A Heisenberg Picture Approach to Classical Measurement-Based Quantum Feedback Control

In this Heisenberg picture approach to classical measurement-based quantum feedback control, we begin with a quantum system which is described by linear quantum stochastic equations of the form (5). In these equations, it is assumed that the components of the output vector all commute with each other and so can be regarded as classical quantities. This can be achieved if each of the components is obtained via a process of homodyne detection from the corresponding electromagnetic field; e.g., see Bachor and Ralph (2004). Also, it is assumed that the input electromagnetic field $w(t)$ can be decomposed as

$$dw(t) = \begin{bmatrix} \beta_u(t)dt + d\tilde{w}_1(t) \\ dw_2(t) \end{bmatrix} \quad (6)$$

where $\beta_u(t)$ represents the classical control input signal, and $\tilde{w}_1(t)$, $w_2(t)$ are quantum Wiener processes. The control signal displaces components of the incoming electromagnetic field acting on the system via the use of an electrooptic modulator; e.g., see Bachor and Ralph (2004).

The classical measurement feedback-based controllers to be considered are classical systems described by stochastic differential equations of the form

$$\begin{aligned} dx_K(t) &= A_K x_K(t)dt + B_K dy(t); \\ \beta_u(t)dt &= C_K x_K(t)dt. \end{aligned} \quad (7)$$

For a given quantum system model (5), the matrices in the controller (7) can be designed using standard classical control theory techniques such as LQG control (see Doherty and Jacobs 1999) or H^∞ control (see James et al. 2008).

Coherent Quantum Feedback Control

Coherent feedback control of a quantum system corresponds to the case in which the controller

itself is a quantum system which is coupled in a feedback interconnection to the quantum system being controlled; e.g., see Lloyd (2000). This type of control by interconnection is closely related to the behavioral interpretation of feedback control; e.g., see Polderman and Willems (1998).

An important approach to coherent quantum feedback control occurs in the case when the quantum system to be controlled is a linear quantum system described by the QSDEs (5). Also, it is assumed that the input field is decomposed as in (6). However in this case, the quantity $\beta_u(t)$ represents a vector of non-commuting operators on the Hilbert space underlying the controller system. These operators are described by the following linear QSDEs, which represent the quantum controller:

$$\begin{aligned} dx_K(t) &= A_K x_K(t)dt + B_K dy(t) + \bar{B}_K d\bar{w}_K(t); \\ dy_K(t) &= C_K x_K(t)dt + \bar{D}_K d\bar{w}_K(t). \end{aligned} \quad (8)$$

Then, the input $\beta_u(t)$ is identified as

$$\beta_u(t) = C_K x_K(t).$$

Here the quantity

$$dw_K(t) = \begin{bmatrix} dy(t) \\ d\bar{w}_K(t) \end{bmatrix} \quad (9)$$

represents the quantum fields acting on the controller quantum system and where $w_K(t)$ corresponds to a quantum Wiener process with a given Itô table. Also, $y(t)$ represents the output quantum fields from the quantum system being controlled. Note that in the case of coherent quantum feedback control, there is no requirement that the components of $y(t)$ commute with each other, and this in fact represents one of the main advantages of coherent quantum feedback control as opposed to classical measurement-based quantum feedback control.

An important requirement in coherent feedback control is that the QSDEs (8) should satisfy the conditions for physical realizability; e.g., see James et al. (2008). Subject to these constraints,

the controller (8) can then be designed according to an H^∞ or LQG criterion; e.g., see James et al. (2008) and Nurdin et al. (2009). In the case of coherent quantum H^∞ control, it is shown in James et al. (2008) that for any controller matrices (A_K, B_K, C_K) , the matrices $(\bar{B}_K, \bar{D}_K)$ can be chosen so that the controller QSDEs (8) are physically realizable. Furthermore, the choice of the matrices $(\bar{B}_K, \bar{D}_K)$ does not affect the H^∞ performance criterion considered in James et al. (2008). This means that the coherent controller can be designed using the same approach as designing a classical H^∞ controller.

In the case of coherent LQG control such as considered in Nurdin et al. (2009), the choice of the matrices $(\bar{B}_K, \bar{D}_K)$ significantly affects the closed loop LQG performance of the quantum control system. This means that the approach used in solving the coherent quantum H^∞ problem given in James et al. (2008) cannot be applied to the coherent quantum LQG problem. To date there exist only some non-convex optimization methods which have been applied to the coherent quantum LQG problem (e.g., see Nurdin et al. 2009; Khodaparastsichani et al. 2017), and the general solution to the coherent quantum LQG control problem remains an open question.

Abstract

The undesirable effects of roll motion of ships (rocking about the longitudinal axis) became noticeable in the mid-nineteenth century when significant changes were introduced

to the design of ships as a result of sails being replaced by steam engines and the arrangement being changed from broad to narrow hulls. The combination of these changes led to lower transverse stability (lower restoring moment for a given angle of roll) with the consequence of larger roll motion. The increase in roll motion and its effect on cargo and human performance lead to the development several control devices that aimed at reducing and controlling roll motion. The control devices most commonly used today are fin stabilizers, rudder, anti-roll tanks, and gyro stabilizers. The use of different types of actuators for control of ship roll motion has been amply demonstrated for over 100 years. Performance, however, can still fall short of expectations because of difficulties associated with control system design, which have proven to be far from trivial due to fundamental performance limitations and large variations of the spectral characteristics of wave-induced roll motion. This short article provides an overview of the fundamentals of control design for ship roll motion reduction. The overview is limited to the most common control devices. Most of the material is based on Perez (Ship motion control. Advances in industrial control. Springer, London, 2005) and Perez and Blanke (Ann Rev Control 36(1):1367–5788, 2012).

Roll damping · Ship motion control

Ship Roll Motion Control Techniques

One of the most commonly used devices to attenuate ship motion are the fin stabilisers. These are small controllable fins located on the bilge of the hull usually amid ships. These devices attain a performance in the range of 60–90 % of roll reduction (root mean square) (Sellars and Martin 1992). They require control systems that sense the vessel's roll motion and act by changing the angle of the fins. These devices are expensive and introduce underwater noise that can affect

sonar performance, they add to propulsion losses, and they can be damaged. Despite this, they are among the most commonly used ship roll motion control device. From a control perspective, highly nonlinear effects (dynamic stall) may appear when operating in severe sea states and heavy rolling conditions (Gaillardie 2002).

During studies of ship damage stability conducted in the late 1800s, it was observed that under certain conditions the water inside the vessel moved out of phase with respect to the wave profile, and thus, the weight of the water on the vessel counteracted the increase of pressure on the hull, hence reducing the net roll excitation moment. This led to the development of fluid anti-roll tank stabilizers. The most common type of anti-roll tank is the U-tank, which comprises two reservoirs, located one on port and one on starboard, connected at the bottom by a duct. Anti-roll tanks can be either passive or active. In passive tanks, the fluid flows freely from side to side. According to the density and viscosity of the fluid used, the tank is dimensioned so that the time required for most of the fluid to flow from side to side equals the natural roll period of the ship. Active tanks operate in a similar manner, but they incorporate a control system that modifies the natural period of the tank to match the actual ship roll period. This is normally achieved by controlling the flow of air from the top of one reservoir to the other. Anti-roll tanks attain a medium to high performance in the range of 20–70 % of roll angle reduction (RMS) (Marzouk and Nayfeh 2009). Anti-roll tanks increase the ship displacement. They can also be used to correct list (steady-state roll angle), and they are the preferred stabilizer for icebreakers.

Rudder-roll stabilization (RRS) is a technique based on the fact that the rudder is located not only aft, but also below the center of gravity of the vessel, and thus the rudder imparts not only yaw but also roll moment. The idea of using the rudder for simultaneous course keeping and roll reduction was conceived in the late 1960s by observations of anomalous behavior of autopilots that did not have appropriate wave filtering – a feature of the autopilot that prevents the rudder from reacting to every single wave; see, for example, Fossen and Perez (2009) for a discussion on

wave filtering. Rudder-roll stabilization has been demonstrated to attain medium to high performance in the range of 50–75 % of roll reduction (RMS) (Baitis et al. 1983; Källström et al. 1988; Blanke et al. 1989; van Amerongen et al. 1990; Oda et al. 1992). The upgrade of the rudder machinery is required to be able to attain slew rates in the range 10–20 deg/s for RRS to have sufficient control authority.

A gyrostabilizer uses the gyroscopic effects of large rotating wheels to generate a roll reducing torque. The use of gyroscopic effects was proposed in the early 1900s as a method to eliminate roll, rather than to reduce it. Although the performance of these systems was remarkable, up to 95 % roll reduction, their high cost, the increase in weight, and the large stress produced on the hull masked their benefits and prevented further developments. However, a recent increase in development of gyrostabilizers has been seen in the yacht industry (Perez and Steinmann 2009).

Fins and rudder give rise to lift forces in proportion to the square of flow velocity past the fin. Hence, roll stabilization by fin or rudder is not possible at low or zero speed. Only U-tanks and gyro devices are able to provide stabilization in these conditions. For further details about the performance of different devices, see Sellars and Martin (1992), and for a comprehensive description of the early development of devices, see Chalmers (1931).

Modeling of Ship Roll Motion for Control Design

The study of roll motion dynamics for control system design is normally done in terms of either one- or four-degrees-of-freedom (DOF) models. The choice between models of different complexity depends on the type of motion control system considered.

For a one-degree-of-freedom (1DOF) case, the following model is used:

$$\dot{\phi} = p, \quad (1)$$

$$I_{xx} \dot{p} = K_h + K_w + K_c, \quad (2)$$

where ϕ is roll angle, p is roll rate, and I_{xx} is rigid-body moment of inertia about the x -axis of a body-fixed coordinate system, where K_h is hydrostatic and hydrodynamic torques, K_w torque generated by wave forces acting on the hull, and K_c the control torques. The hydrodynamic torque can be approximated by the following parametric model: $K_h \approx K_{\dot{p}} \dot{p} + K_p p + K_{p|p|} p|p| + K(\phi)$. The first term represents a hydrodynamic torque in roll due to pressure change that is proportional to the roll accelerations, and the coefficient $K_{\dot{p}}$ is called roll added mass (inertia). The second term is a damping term, which captures forces due to wave making and linear skin friction, and the coefficient K_p is a linear damping coefficient. The third term is a nonlinear damping term, which captures forces due to viscous effects. The last term is the restoring torque due to gravity and buoyancy.

For a 4DOF model (surge, sway, roll, and yaw), motion variables considered are $\eta = [\phi \ \psi]^T$, $v = [u \ v \ p \ r]^T$, $\tau_i = [X \ Y \ K \ N]^T$, where ψ is the yaw angle, the body-fixed velocities are u -surge and v -sway, and r is the yaw rate. The forces and torques are X -surge, Y -sway, K -roll, and N -yaw. With these variables, the following mathematical model is usually considered:

$$\dot{\eta} = \mathbf{J}(\eta) v, \quad (3)$$

$$\mathbf{M}_{RB} \dot{v} + \mathbf{C}_{RB}(v)v = \tau_h + \tau_c + \tau_d, \quad (4)$$

where $\mathbf{J}(\eta)$ is a kinematic transformation, $\mathbf{M}_{RB}$ is the rigid-body inertia matrix that corresponds to expressing the inertia tensor in body-fixed coordinates, $\mathbf{C}_{RB}(v)$ is the rigid-body Coriolis and centripetal matrix, and τ_h , τ_c , and τ_d represent the hydrodynamic, control, and disturbance vector of force components and torques, respectively.

The hydrostatic and hydrodynamic forces are $\tau_h \approx -\mathbf{M}_A \dot{v} - \mathbf{C}_A(v)v - \mathbf{D}(v)v - \mathbf{K}(\phi)$. The first two terms have origin in the motion of a vessel in an irrotational flow in a nonviscous fluid. The third term corresponds to damping forces due to potential (wave making), skin friction, vortex shedding, and circulation (lift and drag). The hydrodynamic effects involved are quite complex, and different approaches based on superposition of either odd-term Taylor expansions or square modulus ($x|x|$) series expan-

sions are usually considered Abkowitz (1964) and Fedyaevsky and Sobolev (1964). The $\mathbf{K}(\phi)$ term represents the restoring forces in roll due to buoyancy and gravity. The 4DOF model captures parameter dependency on ship speed as well as the couplings between steering and roll, and it is useful for controller design. For additional details about mathematical model of marine vehicles, see Fossen (2011).

Wave-Disturbance Models

The action of the waves creates changes in pressure on the hull of the ship, which translate into forces and moments. It is common to model the ship motion response due to waves within a linear framework and to obtain two frequency-response functions (FRF), wave to excitation $F_i(j\omega, U, \chi)$ and wave to motion $H_i(j\omega, U, \chi)$ response functions, where i indicates the degree of freedom. These FRF depend on the wave frequency, the ship speed, and the angle χ at which the waves encounter the ship – this is called the encounter angle.

The wave elevation in deep water is approximately a stochastic process that is zero mean, stationary for short periods of time, and Gaussian (Haverre and Moan 1985). Under these assumptions, the wave elevation ζ is fully described by a power spectral density $\Phi_{\zeta\zeta}(\omega)$. With a linear response assumption, the power spectral density of wave to excitation force and wave to motion can be expressed as

$$\Phi_{FF,i}(j\omega) = |F_i(j\omega, U, \chi)|^2 \Phi_{\zeta\zeta}(j\omega),$$

$$\Phi_{\eta\eta,i}(j\omega) = |H_i(j\omega, U, \chi)|^2 \Phi_{\zeta\zeta}(j\omega).$$

These spectra are models of the wave-induced forces and motions, respectively, from which it is common to generate either time series of wave excitation forces in terms of the encounter frequency to be used as input disturbances in simulation models or time series of wave-induced motion to be used as output disturbance; see, for example, Perez (2005) and references herein.

Roll Motion Control and Performance Limitations

The analysis of performance of ship roll motion control by means of force actuators is usually

conducted within a linear framework by linearizing the models. For a SISO loop where the wave-induced roll motion is considered an output disturbance, the Bode integral constraint applies. This imposes restrictions on one's freedom to shape the closed-loop transfer function to attenuate the motion due to the wave-induced forces in different frequency ranges. These results have important consequences on the design of a roll motion control system since the frequency of the waves seen from the vessel changes significantly with the sea state, the speed of the vessel, and the wave encounter angle. The changing characteristics on open-loop roll motion in conjunction with the Bode integral constraint make the control design challenging since roll amplification may occur if the control design is not done properly. For some roll motion control problems, like using the rudder for simultaneous roll attenuation and heading control, the system presents non-minimum phase dynamics. In this case, the trade-off of reduced sensitivity vs. amplification of roll motion is dominating at frequencies close to the non-minimum phase zero – a constraint with origin in the Poisson integral (Hearns and Blanke 1998); see also Perez (2005).

It should be noted that non-minimum phase dynamics also occurs with fin stabilizers, when the stabilizers are located aft of the center of gravity. With the fins at this location, they behave like a rudder and introduce non-minimum phase dynamics and heading interference at low wave-excitation frequencies. These aspects of fin location were discussed by Lloyd (1989).

The above discussion highlights general design constraints that apply to roll motion control systems in terms of the dynamics of the vessel and actuator. In addition to these constraints, one needs also to account for limitations in actuator slew rate and angle.

Controls Techniques Used in Different Roll Control Systems

Fin Stabilizers

In regard to fin stabilizers, the control design is commonly addressed using the 1DOF model (1) and (2). The main issues associated with control

design are the parametric uncertainty in model and the Bode integral constraint. This integral constraint can lead to roll amplification due to changes in the spectrum of the wave-induced roll moment with sea state and sailing conditions (speed and encounter angle). Fin machinery is designed so that the rate of the fin motion is fast enough, and actuator rate saturation is not an issue in moderate sea states. The fins could be used to correct heeling angles (steady-state roll) when the ship makes speed, but this is avoided due to added resistance. If it is used, integral action needs to include anti-windup. In terms of control strategies, PID, $\mathcal{H}_\infty$, and LQR techniques have been successfully applied in practice. Highly nonlinear effects (dynamic stall) may appear when operating in severe sea states and heavy rolling conditions, and proposals for applications of model predictive control have been put forward to constraint the effective angle of attack of the fins. In addition, if the fins are located too far aft along the ship, the dynamic response from fin angle to roll can exhibit non-minimum phase dynamics, which can limit the performance at low encounter frequencies. A thorough review of the control literature can be found in Perez and Blanke (2012).

Rudder-Roll Stabilization

The problem of rudder-roll stabilization requires the 4DOF model (3) and (4), which captures the interaction between roll, sway, and yaw together with the changes in the hydrodynamic forces due to the forward speed. The response from rudder to roll is non-minimum phase (NMP), and the system is characterized by further constraints due to the single-input-two-output nature of the control problem – attenuate roll without too much interference with the heading. Studies of fundamental limitations due to NMP dynamics have been approached using standard frequency-domain tools by Hearn and Blanke (1998) and Perez (2005). A characterization of the trade-off between roll reduction vs. increase of interference was part of the controller design in Stoustrup et al. (1994). Perez (2005) determined the limits obtainable using optimal control with full disturbance information. The latter also incorporated constraints due to the limiting authority of the

control action in rate and magnitude of rudder machinery and stall conditions of the rudder. The control design for rudder-roll stabilization has been addressed in practice using PID, LQG, and $\mathcal{H}_\infty$ and standard frequency-domain linear control designs. The characteristics of limited control authority were solved by van Amerongen et al. (1990) using automatic gain control. In the literature, there have been proposals put forward for the use of model predictive control, QFT, sliding-mode nonlinear control, and autoregressive stochastic control. Combined use of fin and rudder has also been investigated. Grimbé et al. (1993) and later Roberts et al. (1997) used $\mathcal{H}_\infty$ control techniques. Thorough comparison of controller performances for warships was published in Crossland (2003). A thorough review of the control literature can be found in Perez and Blanke (2012).

Gyrostabilizers

Using a single gimbal suspension gyrostabilizer for roll damping control, the coupled vessel-roll-gyro model can be modeled as follows:

$$\dot{\phi} = p, \quad (5)$$

$$K_{\dot{p}} \dot{p} + K_p p + K_{\phi} \phi = K_w - K_g \dot{\alpha} \cos \alpha \quad (6)$$

$$I_p \ddot{\alpha} + B_p \dot{\alpha} + C_p \sin \alpha = K_g p \cos \alpha + T_p, \quad (7)$$

where (6) represents the 1DOF roll dynamics and (7) represents the dynamics of the gyrostabilizer about the axis of the gimbal suspension, where α is the gimbal angle, equivalent to the precession angle for a single gimbal suspension, I_p is gimbal and wheel inertia about the gimbal axis, B_p is the damping, and C_p is a restoring term of the gyro about the precession axis due to location of the gyro center of mass relative to the precession axis (Arnold and Maunder 1961). T_p is the control torque applied to the gimbal. The use of twin counter-spinning wheels prevents gyroscopic coupling with other degrees of freedom. Hence, the control design for gyrostabilizers can be based on a linear single-degree-of-freedom model for roll.

The wave-induced roll moment K_w excites the roll motion. As the roll motion develops, the roll rate p induces a torque along the precession axis

of the gyrostabilizer. As the precession angle α develops, there is reaction torque done on the vessel that opposes the wave-induced moment. The latter is the roll stabilizing torque, $X_g \triangleq -K_g \dot{\alpha} \cos \alpha \approx -K_g \dot{\alpha}$. This roll torque can only be controlled indirectly through the precession dynamics in (7) via T_p . In the model above, the spin angular velocity ω_{spin} is controlled to be constant; hence the wheels' angular momentum $K_g = I_{spin} \omega_{spin}$ is constant.

The precession control torque T_p is used to control the gyro. As observed by Sperry (Chalmers 1931), the intrinsic behavior of the gyrostabilizer is to use roll rate to generate a roll torque. Hence, one could design a precession torque controller such that from the point of view of the vessel, the gyro behaves as damper. Depending on how precession torque is delivered, it may be necessary to constraint precession angle and rate. This problem has been recently considered in Donaire and Perez (2013) using passivity-based control.

U-tanks

U-tanks can be passive or active. Roll reduction is achieved by attempting to transfer energy from the roll motion to motion of liquid within the tank and using the weight of the liquid to counteract the wave excitation moment. A key aspect of the design is the dimension and geometry of the tank to ensure that there is enough weight due to the displaced liquid in the tank and that the oscillation of the fluid in the tank matches the vessel natural frequency in roll; see Holden and Fossen (2012) and references herein. The design of the U-tank can ensure a single-frequency matching, at which the performance is optimized, and for this frequency the roll natural frequency is used. As the frequency of roll motion departs from this, a degradation of roll reduction occurs. Active U-tanks use valves to control the flow of air from the top of the reservoirs to extend the frequency matching in sailing conditions in which the roll dominant frequency is lower than the roll natural frequency – the flow of air is used to delay the motion of the liquid from one reservoir to the other. This control is achieved by detecting the dominant roll frequency and using this infor-

mation to control the air flow from one reservoir to the other. If the roll dominant frequency is higher than the roll natural frequency, the U-tank is used in passive mode, and the standard roll reduction degradation occurs.

Summary and Future Directions

This article provides a brief summary of control aspects for the most common ship roll motion control devices. These aspects include the type of mathematical models used to design and analyze the control problem, the inherent fundamental limitations and the constraints that some of the designs are subjected to, and the performance that can be expected from the different devices. As an outlook, one of the key issues in roll motion control is the model uncertainty and the adaptation to the changes in the environmental conditions. As the vessel changes speed and heading, or as the seas build up or abate, the dominant frequency range of the wave-induced forces changes significantly. Due to the fundamental limitations discussed, a nonadaptive controller may produce roll amplification rather than roll reduction. This topic has received some attention in the literature via multi-mode control switching, but further work in this area could be beneficial. In the recent years, new devices have appeared for stabilization at zero speed, like flapping fins and rotating cylinders. Also the industry's interest in roll gyro-stabilizers has been re-ignited. The investigation of control designs for these devices has not yet received much attention within the control community. Hence, it is expected that this will create a potential for research activity in the future.

Control Structure Selection

Sigurd Skogestad

Department of Chemical Engineering,
Norwegian University of Science and
Technology (NTNU), Trondheim, Norway

Abstract

Control structure selection deals with selecting what to control (outputs), what to measure and what to manipulate (inputs), and also how to split the controller in a hierarchical and decentralized manner. The most important issue is probably the selection of the controlled variables (outputs), $CV = Hy$, where y are the available measurements and H is a degree of freedom that is seldom treated in a systematic manner by control engineers. This entry discusses how to find H for both for the upper (slower) economic layer and the lower (faster) regulatory layer in the control hierarchy. Each layer may be split in a decentralized fashion. Systematic approaches for input/output (IO) selection are presented.

Keywords

Control configuration · Control hierarchy · Control structure design · Decentralized control · Economic control · Input-output controllability · Input/output selection · Plantwide control · Regulatory control · Supervisory control

Introduction

Consider the generalized controller design problem in Fig. 1 where P denotes the generalized plant model. Here, the objective is to design the controller K , which, based on the sensed outputs v , computes the inputs (MVs) u such that the variables z are kept small, in spite of variations in the variables w , which include disturbances (d), varying setpoints/references (CV_s) and measurement noise (n),

$$w = [d, CV_s, n]$$

The variables z , which should be kept small, typically include the control error for the selected controlled variables (CV) plus the plant inputs (u),

$$z = [CV - CV_s; u]$$

The variables v , which are the inputs to the controller, include all known variables, including measured outputs (y_m), measured disturbances (d_m) and setpoints,

$$v = [y_m; d_m; CV_s].$$

The cost function for designing the optimal controller K is usually the weighted control error, $J' = ||W'z||$. The reason for using a prime on J (J'), is to distinguish it from the economic cost J which we later use for selecting the controlled variables (CV).

Notice that it is assumed in Fig. 1 that we know what to measure (v), manipulate (u), and, most importantly, which variables in z we would like to keep at setpoints (CV), that is, we have assumed a given control structure. The term “control structure selection” (CSS) and its synonym “control

Control Structure Selection, Fig. 1 General formulation for designing the controller K . The plant P is controlled by manipulating u , and is disturbed by the signals w . The controller uses the measurements v , and the control objective is to keep the outputs (weighted control error) z as small as possible

structure design” (CSD) is associated with the overall *control philosophy* for the system with emphasis on the *structural decisions* which are a prerequisite for the controller design problem in Fig. 1:

1. *Selection of controlled variables* (CVs, “outputs,” included in z in Fig. 1)
2. *Selection of manipulated variables* (MVs, “inputs,” u in Fig. 1)
3. *Selection of measurements* y (included in v in Fig. 1)
4. *Selection of control configuration* (structure of overall controller K that interconnects the controlled, manipulated and measured variables; structure of K in Fig. 1)
5. *Selection of type of controller* K (PID, MPC, LQG, H-infinity, etc.) and objective function (norm) used to design and analyze it.

Decisions 2 and 3 (selection of u and y) are sometimes referred to as the input/output (IO) selection problem. In practice, the controller (K) is usually divided into several layers, operating on different time scales (see Fig. 2), which implies that we in addition to selecting the (primary) controlled variables ($CV_1 \equiv CV$) must also select the (secondary) variables that interconnect the layers (CV_2).

Control structure selection includes all the *structural* decisions that the engineer needs to make when designing a control system, but it does not involve the actual design of each individual controller block. Thus, it involves the deci-

Control Structure Selection, Fig. 2 Typical control hierarchy, as illustrated for a process plant

sions necessary to make a block diagram (Fig. 1; used by control engineers) or process & instrumentation diagram (used by process engineers) for the entire plant, and provides the starting point for a detailed controller design.

The term “plantwide control,” which is a synonym for “control structure selection,” is used in the field of process control. Control structure selection is particularly important for process control because of the complexity of large processing plants, but it applies to all control applications, including vehicle control, aircraft control, robotics, power systems, biological systems, social systems, and so on.

It may be argued that control structure selection is more important than the controller design itself. Yet, control structure selection is hardly covered in most control courses. This is probably related to the complexity of the problem, which requires the knowledge from several engineering fields. In the mathematical sense, the control

structure selection problem is a formidable combinatorial problem which involves a large number of discrete decision variables.

Overall Objectives for Control and Structure of the Control Layer

The starting point for control system design is to define clearly the operational objectives. There are usually two main objectives for control:

1. Longer-term economic operation (minimize economic cost J subject to satisfying operational constraints)
2. Stability and short-term regulatory control

The first objective is related to “making the system operate as intended,” where economics are an important issue. Traditionally, control engineers have not been much involved in this step. The second objective is related to “making sure the system stays operational,” where stability and robustness are important issues, and this has traditionally been the main domain of control engineers. In terms of designing the control system, the second objective (stabilization) is usually considered first. An example is bicycle riding; we first need to learn how to stabilize the bicycle (regulation), before trying to use it for something useful (optimal operation), like riding to work and selecting the shortest path.

We use the term “economic cost,” because usually the cost function J can be given a monetary value, but more generally, the cost J could be any scalar cost. For example, the cost J could be the “environmental impact” and the economics could then be given as constraints.

In theory, the optimal strategy is to combine the control tasks of optimal economic operation and stabilization/regulation in a single centralized controller K , which at each time step collects all the information and computes the optimal input changes. In practice, simpler controllers are used. The main reason for this is that in most cases one can obtain acceptable control performance with simple structures, where each controller block involves only a few variables. Such control sys-

tems can be designed and tuned with much less effort, especially when it comes to the modeling and tuning effort.

So how are large-scale systems controlled in practise? Usually, the controller K is decomposed into several subcontrollers, using two main principles

- *Decentralized (local) control*. This “horizontal decomposition” of the control layer is usually based on separation in space, for example, by using local control of individual units.
- *Hierarchical (cascade) control*. This “vertical decomposition” is usually based on time scale separation, as illustrated for a process plant in Fig. 2. The upper three layers in Fig. 2 deal explicitly with economic optimization and are not considered here. We are concerned with the two lower *control layers*, where the main objective is to track the setpoints specified by the layer above.

In accordance with the two main objectives for control, the control layer is in most cases divided hierarchically in two layers (Fig. 2):

1. A “slow” supervisory (economic) layer
2. A “fast” regulatory (stabilization) layer

Another reason for the separation in two control layers, is that the tasks of economic operation and regulation are fundamentally different. Combining the two objectives in a single cost function, which is required for

designing a single centralized controller K , is like trying to compare apples and oranges. For example, how much is an increased stability margin worth in monetary units [\$]? Only if there is a reasonable benefit in combining the two layers, for example, because there is limited time scale separation between the tasks of regulation and optimal economics, should one consider combining them into a single controller.

Notation and Matrices H_1 and H_2 for Controlled Variable Selection

The most important notation is summarized in Table 1 and Fig. 3. To distinguish between the two control layers, we use “1” for the upper supervisory (economic) layer and “2” for the regulatory layer, which is “secondary” in terms of its place in the control hierarchy.

There is often limited possibility to select the input set (u) as it is usually constrained by the plant design. However, there may be a possibility to add inputs or to move some to another location, for example, to avoid saturation or to reduce the time delay and thus improve the input-output controllability.

There is much more flexibility in terms of output selection, and the most important structural decision is related to the selection of controlled variables in the two control layers, as given by the decision matrices H_1 and H_2 (see Fig. 3).

$$CV_1 = H_1 y$$

Control Structure Selection, Table 1 Important notation

$u = [u_1; u_2]$ = set of all available physical plant inputs
u_1 = inputs used directly by supervisory control layer
u_2 = inputs used by regulatory layer
y_m = set of all measured outputs
$y = [y_m; u]$ = combined set of measurements and inputs
y_2 = controlled outputs in regulatory layer (subset or combination of y); $\dim(y_2) = \dim(u_2)$
$CV_1 = H_1 y$ = controlled variables in supervisory layer; $\dim(CV_1) = \dim(u)$
$CV_2 = [y_2; u_1] = H_2 y$ = controlled variables in regulatory layer; $\dim(CV_2) = \dim(u)$
$MV_1 = CV_{2s} = [y_{2s}; u_1]$ = manipulated variables in supervisory layer; $\dim(MV_1) = \dim(u)$
$MV_2 = u_2$ = manipulated variables in regulatory layer; $\dim(MV_2) = \dim(u_2) \leq \dim(u)$

Control Structure Selection, Fig. 3 Block diagram of a typical control hierarchy, emphasizing the selection of controlled variables for supervisory (economic) control ($CV_1 = H_1 y$) and regulatory control ($CV_2 = H_2 y$)

$$CV_2 = H_2 y$$

Note from the definition in Table 1 that $y = [y_m; u]$. Thus, y includes, in addition to the candidate measured outputs (y_m), also the physical inputs u . This allows for the possibility of selecting an input u as a “controlled” variable, which means that this input is kept constant (or, more precisely, the input is left “unused” for control in this layer).

In general, H_1 and H_2 are “full” matrices, allowing for measurement combinations as controlled variables. However, for simplicity, especially in the regulatory layer, we often prefer to control individual measurements, that is, H_2 is usually a “selection matrix,” where each row in H_2 contains one 1-element (to identify the selected variable) with the remaining elements set to 0. In this case, we can write $CV_2 = H_2 y = [y_2; u_1]$, where y_2 denotes the actual controlled variables in the regulatory layer, whereas u_1 denotes the “unused” inputs (u_1), which are left as degrees of freedom for the supervisory layer. Note that this indirectly determines the

inputs u_2 used in the regulatory layer to control y_2 , because u_2 is what remains in the set u after selecting u_1 . To have a simple control structure, with as few regulatory loops as possible, it is desirable that H_2 is selected such that there are many inputs (u_1) left “unused” in the regulatory layer.

Example. Assume there are three candidate output measurements (temperatures T) and two inputs (flowrates q),

$$y_m = [T_a T_b T_c], \quad u = [q_a q_b]$$

and we have by definition $y = [y_m; u]$. Then the choice

$$H_2 = [0 \ 1 \ 0 \ 0 \ 0; \ 0 \ 0 \ 0 \ 0 \ 1]$$

means that we have selected $CV_2 = H_2 y = [T_b; q_b]$. Thus, $u_1 = q_b$ is an unused input for regulatory control, and in the regulatory layer we close one loop, using $u_2 = q_a$ to control $y_2 = T_b$. If we instead select

$$H_2 = [1 \ 0 \ 0 \ 0 \ 0; \ 0 \ 0 \ 1 \ 0 \ 0]$$

then we have $CV_2 = [T_a; T_c]$. None of these are inputs, so u_1 is an empty set in this case. This means that we need to close two regulatory loops, using $u_2 = [q_a; q_b]$ to control $y_2 = [T_a; T_c]$.

Supervisory Control Layer and Selection of Economic Controlled Variables (CV_1)

Some objectives for the supervisory control layer are given in Table 2. The main structural issue for the supervisory control layer, and probably the most important decision in the design of any control system, is the selection of the primary (economic) controlled variable CV_1 . In many cases, a good engineer can make a reasonable choice based on process insight and experience. However, the control engineer must realize that this is a critical decision. The main rules and issues for selecting CV_1 are

Control Structure Selection, Table 2 Objectives of supervisory control layer

O1. Control primary “economic” variables CV_1 at setpoint using as degrees of freedom MV_1 , which includes the setpoints to the regulatory layer ($y_{2s} = CV_{2s}$) as well as any “unused” degrees of freedom (u_1)
O2. Switch controlled variables (CV_1) depending on operating region, for example, because of change in active constraints
O3. Supervise the regulatory layer, for example, to avoid input saturation (u_2), which may destabilize the system
O4. Coordinate control loops (multivariable control) and reduce effect of interactions (decoupling)
O5. Provide feedforward action from measured disturbances
O6. Make use of additional inputs, for example, to improve the dynamic performance (usually combined with input readjusting control) or to extend the steady-state operating range (split range control)
O7. Make use of extra measurements, for example, to estimate the primary variables CV_1

 CV_1 Rule 1. Control active constraints (almost always)

- Active constraints may often be identified by engineering insight, but more generally requires optimization based on a detailed model.

For example, consider the problem of minimizing the driving time between two cities (cost $J = T$). There is a single input ($u = \text{fuel flow } f[\text{l/s}]$) and the optimal solution is often constrained. When driving a fast car, the active constraint may be the speed limit ($CV_1 = v[\text{km/h}]$ with setpoint $v_{\max}$, e.g., $v_{\max} = 100 \text{ km/h}$). When driving an old car, the active constraint may be the maximum fuel flow ($CV_1 = f[\text{l/s}]$ with setpoint $f_{\max}$). The latter corresponds to an input constraint ($u_{\max} = f_{\max}$) which is trivial to implement (“full gas”); the former corresponds to an output constraint ($y_{\max} = v_{\max}$) which requires a controller (“cruise control”).

- For “hard” output constraints, which cannot be violated at any time, we need to introduce a *backoff* (safety margin) to guarantee feasibility. The backoff is defined as the difference between the optimal value and the actual setpoint, for example, we need to back off from the speed limit because of the possibility for measurement error and imperfect control

$$CV_{1,s} = CV_{1,\max} - \text{backoff}$$

For example, to avoid exceeding the speed limit of 100 km/h, we may set $\text{backoff} = 5 \text{ km/h}$, and use a setpoint $v_s = 95 \text{ km/h}$ rather than 100 km/h.

 CV_1 Rule 2. For the remaining unconstrained degrees of freedom, look for “self-optimizing” variables which when held constant, indirectly lead to close-to-optimal operation, in spite of disturbances.

- Self-optimizing variables ($CV_1 = H_1 y$) are variables which when kept constant, indirectly (through the action of the feedback control system) lead to close-to optimal adjustment of the inputs (u) when there are disturbances (d).
- An ideal self-optimizing variable is the gradient of the cost function with respect to the unconstrained input. $CV_1 = dJ/du = J_u$
- More generally, since we rarely can measure the gradient J_u , we select $CV_1 = H_1 y$. The selection of a good H_1 is a nontrivial task, but some quantitative approaches are given below.

For example, consider again the problem of driving between two cities, but assume that the objective is to minimize the total fuel, $J = V[\text{liters}]$. Here, driving at maximum speed will consume too much fuel, and driving too slow is also nonoptimal. This is an unconstrained optimization problem, and identifying a good CV_1 is not obvious. One option is to maintain

a constant speed ($CV_1 = v$), but the optimal value of v may vary depending on the slope of the road. A more “self-optimizing” option, could be to keep a constant fuel rate ($CV_1 = f[l/s]$), which will imply that we drive slower uphill and faster downhill. More generally, one can control combinations, $CV_1 = H_1 y$ where H_1 is a “full” matrix.

CV₁ Rule 3. For the unconstrained degrees of freedom, one should *never* control a variable that reaches its maximum or minimum value at the optimum, for example, never try to control directly the cost J . Violation of this rule gives either infeasibility (if attempting to control J at a lower value than $J_{\min}$) or nonuniqueness (if attempting to control J at higher value than $J_{\min}$).

Assume again that we want to minimize the total fuel needed to drive between two cities, $J = V[l]$. Then one should avoid fixing the total fuel, $CV_1 = V[l]$, or, alternatively, avoid fixing the fuel consumption (“gas mileage”) in liters pr. km ($CV_1 = f[l/km]$). Attempting to control the fuel consumption $[l/km]$ below the car’s minimum value is obviously not possible (infeasible). Alternatively, attempting to control the fuel consumption above its minimum value has two possible solutions; driving slower or faster than the optimum. Note that the policy of controlling the fuel rate $f[l/s]$ at a fixed value will never become infeasible.

For CV₁-Rule 2, it is always possible to find good variable combinations (i.e., H_1 is a “full” matrix), at least locally, but whether or not it is possible to find good individual variables (H_1 is a selection matrix), is not obvious. To help identify potential “self-optimizing” variables ($CV_1 = c$), the following requirements may be used:

Requirement 1. The optimal value of c is insensitive to disturbances, that is, $dc_{\text{opt}}/dd = H_1 F$ is small. Here $F = dy_{\text{opt}}/dd$ is the optimal sensitivity matrix (see below).

Requirement 2. The variable c is easy to measure and control accurately

Requirement 3. The value of c is sensitive to changes in the manipulated variable, u ; that is,

the gain, $G = HG^y$, from u to c is large (so that even a large error in controlled variable, c , results in only a small variation in u .) Equivalently, the optimum should be “flat” with respect to the variable, c . Here $G^y = dy/du$ is the measurement gain matrix (see below).

Requirement 4. For cases with two or more controlled variables c , the selected variables should not be closely correlated.

All four requirements should be satisfied. For example, for the operation of a marathon runner, the heart rate may be a good “self-optimizing” controlled variable c (to keep at constant set-point). Let us check this against the four requirements. The optimal heart rate is weakly dependent on the disturbances (requirement 1) and the heart rate is easy to measure (requirement 2). The heart rate is quite sensitive to changes in power input (requirement 3). Requirement 4 does not apply since this is a problem with only one unconstrained input (the power). In summary, the heart rate is a good candidate.

Regions and switching. If the optimal active constraints vary depending on the disturbances, new controlled variables (CV_1) must be identified (offline) for each active constraint region, and on-line switching is required to maintain optimality. In practise, it is easy to identify when to switch when one reaches a constraint. It is less obvious when to switch out of a constraint, but actually one simply has to monitor the value of the unconstrained CVs from the neighbouring regions and switch out of the constraint region when the unconstrained CV reaches its setpoint.

In general, one would like to simplify the control structure and reduce need for switching. This may require using a suboptimal CV_1 in some regions of active constraints. In this case, the setpoint for CV_1 may not be its nominally optimal value (which is the normal choice), but rather a “robust setpoint” (with backoff) which reduces the loss when we are outside the nominal constraint region.

Structure of supervisory layer. The supervisory layer may either be centralized, e.g., using

model predictive control (MPC), or decomposed into simpler subcontrollers using standard elements, like decentralized control (PID), cascade control, selectors, decouplers, feedforward elements, ratio control, split range control, and input midrange control (also known as input resetting, valve position control or habituating control). In theory, the performance is better with the centralized approach (e.g., MPC), but the difference can be small when designed by a good engineer. The main reasons for using simpler elements is that (1) the system can be implemented in the existing “basic” control system, (2) it can be implemented with little model information, and (3) it can be build up gradually. However, such systems can quickly become complicated and difficult to understand for other than the engineer who designed it. Therefore, model-based centralized solutions (MPC) are often preferred because the design is more systematic and easier to modify.

Quantitative Approach for Selecting Economic Controlled Variables, CV_1

A quantitative approach for selecting economic controlled variables is to consider the effect of the choice $CV_1 = H_1 y$ on the economic cost J when disturbances d occur. One should also include noise/errors (n^y) related to the measurements and inputs.

Step S1. *Define operational objectives (economic cost function J and constraints)*

We first quantify the operational objectives in terms of a scalar cost function J [\$/s] that should be minimized (or equivalently, a scalar profit function, $P = -J$, that should be maximized). For process control applications, this is usually easy, and typically we have

$$J = \text{cost feed} + \text{cost utilities (energy)} \\ - \text{value products [$/s]}$$

Note that the economic cost function J is used to *select* the controlled variables (CV_1), and another cost function (J'), typically involving the deviation in CV_1 from their optimal

setpoints CV_{1s} , is used for the actual controller design (e.g., using MPC).

Step S2. *Find optimal operation for expected disturbances*

Mathematically, the optimization problem can be formulated as

$$\text{minimize } J(u, x, d)$$

subject to:

$$\text{Model equations: } dx/dt = f(u, x, d)$$

$$\text{Operational constraints: } g(u, x, d) \leq 0$$

In many cases, the economics are determined by the steady-state behavior, so we can set $dx/dt = 0$. The optimization problem should be resolved for the expected disturbances (d) to find the truly optimal operation policy, $u_{\text{opt}}(d)$. The nominal solution (d_{nom}) may be used to obtain the setpoints (CV_{1s}) for the selected controlled variables. In practise, the optimum input $u_{\text{opt}}(d)$ cannot be realized, because of model error and unknown disturbances d , so we use a feedback implementation where u is adjusted to keep the selected variables CV_1 at their nominally optimal setpoints.

Together with obtaining the model, the optimization step S2 is often the most time consuming step in the entire plantwide control procedure.

Step S3. *Select supervisory (economic) controlled variables, CV_1*

CV_1 -Rule 1: Control Active Constraints

A primary goal for solving the optimization problem is to find the expected regions of active constraints, and a constraint is said to be “active” if $g = 0$ at the optimum. The optimally active constraints will vary depending on disturbances (d) and market conditions (prices).

CV_1 -Rule 2: Control Self-Optimizing Variables

After having identified (and controlled) the active constraints, one should consider the remaining lower-dimension unconstrained optimization

problem, and for the remaining unconstrained degrees of freedom one should search for *control “self-optimizing” variables* c .

1. **“Brute force” approach.** Given a set of controlled variables $CV_1 = c = H_1 y$, one computes the cost $J(c, d)$ when we keep c constant ($c = c_s + H_1 n^y$) for various disturbances (d) and measurement errors (n^y). In practise, this is done by running a large number of steady-state simulations to try to cover the expected future operation.
2. **“Local” approaches** based on a quadratic approximation of the cost J . Linear models are used for the effect of u and d on y .

$$y = G^y u + G_d^y d$$

This is discussed in more detail in Alstad et al. (2009) and references therein. The main local approaches are:

- 2A. **Maximum gain rule: maximize the minimum singular value of $G = H_1 G^y$.** In other words, the maximum gain rule, which essentially is a quantitative version of Requirements 1, 3 and 4 given above, says that one should control “sensitive” variables, with a large scaled gain G from the inputs (u) to $c = H_1 y$. This rule is good for pre-screening and also yields good insight.
- 2B. **Nullspace method.** This method yields optimal measurement combinations for the case with no noise, $n^y = 0$. One must first obtain the optimal measurement sensitivity matrix F , defined as

$$F = dy^{\text{opt}}/dd.$$

Each column in F expresses the optimal change in the y 's when the independent variable (u) is adjusted so that the system remains optimal with respect to the disturbance d . Usually, it is simplest to obtain F numerically by optimizing the model. Alternatively, we can obtain F from a quadratic approximation of the cost function

$$F = G_d^y - G^y J_{uu}^{-1} J_{ud}$$

Then, assuming that we have at least as many (independent) measurements y as the sum of the number of (independent) inputs (u) and disturbances (d), the optimal is to select $c = H_1 y$ such that

$$H_1 F = 0$$

Note that H_1 is a nonsquare matrix, so $H_1 F = 0$ does not require that $H_1 = 0$ (which is a trivial uninteresting solution), but rather that H_1 is in the nullspace of F^T .

- 2C. **Exact local method (loss method).** This extends the nullspace method to include noise (n^y) and allows for any number of measurements. The noise and disturbances are normalized by introducing weighting matrices W_{ny} and W_d (which have the expected magnitudes along the diagonal) and then the expected loss, $L = J - J_{\text{opt}}(d)$, is minimized by selecting H_1 to solve the following problem

$$\min_{H_1} \|M(H_1)\|_2$$

where $\| \cdot \|_2$ denotes the Frobenius norm and

$$\begin{aligned} M(H_1) &= J_{uu}^{1/2} (H_1 G^y)^{-1} H_1 Y, Y \\ &= [F W_d W_{ny}]. \end{aligned}$$

Note here that the optimal choice with $W_{ny} = 0$ (no noise) is to choose H_1 such that $H_1 F = 0$, which is the nullspace method. For the general case, when H_1 is a “full” matrix, this is a convex problem and the optimal solution is $H_1^T = (Y Y')^{-1} G^y Q$ where Q is any nonsingular matrix.

Regulatory Control Layer

The main purpose of the regulatory layer is to “stabilize” the plant, preferably using a *simple* control structure (e.g., single-loop PID controllers) which does not require changes

during operation. “Stabilize” is here used in a more extended sense to mean that the process does not “drift” too far away from acceptable operation when there are disturbances. The regulatory layer should make it possible to use a “slow” supervisory control layer that does not require a detailed model of the high-frequency dynamics. Therefore, in addition to track the setpoints given by the supervisory layer (e.g., MPC), the regulatory layer may directly control primary variables (CV_1) that require fast and tight control, like economically important active constraints.

In general, the design of the regulatory layer involves the following structural decisions:

1. Selection of controlled outputs y_2 (among all candidate measurements y_m).
2. Selection of inputs $MV_2 = u_2$ (a subset of all available inputs u) to control the outputs y_2 .
3. Pairing of inputs u_2 and outputs y_2 (since decentralized control is normally used).

Decisions 1 and 2 combined (IO selection) is equivalent to selecting H_2 (Fig. 3). Note that we do not “use up” any degrees of freedom in the regulatory layer because the set points (y_{2s}) become manipulated variables (MV_1) for the supervisory layer (see Fig. 3). Furthermore, since the set points are set by the supervisory layer in a cascade manner, the system eventually approaches the same steady-state (as defined by the choice of economic variables CV_1) regardless of the choice of controlled variables in the regulatory layer.

The inputs for the regulatory layer (u_2) are selected as a subset of all the available inputs (u). For stability reasons, one should avoid input saturation in the regulatory layer. In particular, one should avoid using inputs (in the set u_2) that are optimally constrained in some disturbance region. Otherwise, in order to avoid input saturation, one needs to include a backoff for the input when entering this operational region, and doing so will have an economic penalty.

In the regulatory layer, the outputs (y_2) are usually selected as individual measurements and they are often not important variables in them-

selves. Rather, they are “extra outputs” that are controlled in order to “stabilize” the system, and their setpoints (y_{2s}) are changed by the layer above, to obtain economical optimal operation. For example, in a distillation column one may control a temperature somewhere in the middle of the column ($y_2 = T$) in order to “stabilize” the column profile. Its setpoint ($y_{2s} = T_s$) is adjusted by the supervisory layer to obtain the desired product composition ($y_1 = c$).

Input-Output (IO) Selection for Regulatory Control (u_2, y_2)

Finding the truly optimal control structure, including selecting inputs and outputs for regulatory control, requires finding also the optimal controller parameters. This is an extremely difficult mathematical problem, at least if the controller K is decomposed into smaller controllers. In this section, we consider some approaches which does not require that the controller parameters be found. This is done by making assumptions related to achievable control performance (controllability) or perfect control.

Before we look at the approaches, note again that the IO-selection for regulatory control may be combined into a single decision, by considering the selection of

$$CV_2 = [y_2; u_1] = H_2 y$$

Here u_1 denotes the inputs that are not used by the regulatory control layer. This follows because we want to use all inputs u for control, so assuming that the set u is given, “selection of inputs u_2 ” (decision 2) is by elimination equivalent to “selection of inputs u_1 .” Note that CV_2 include all variables that we keep at desired (constant) values within the fast time horizon of the regulatory control layer, including the “unused” inputs u_1

Survey by Van de Wal and Jager

Van de Wal and Jager provide an overview of methods for input-output selection, some of which include:

1. “Accessibility” based on guaranteeing a cause–effect relationship between the selected inputs (u_2) and outputs (y_2). Use of such measures may eliminate unworkable control structures.
2. “State controllability and state observability” to ensure that any unstable modes can be stabilized using the selected inputs and outputs.
3. “Input-output controllability” analysis to ensure that y_2 can be acceptably controlled using u_2 . This is based on scaling the system, and then analysing the transfer matrices $G_2(s)$ (from u_2 to y_2) and G_{d2} (from expected disturbances d to y_2). Some important controllability measures are right half plane zeros (unstable dynamics of the inverse), condition number, singular values, relative gain array, etc. One problem here is that there are many different measures, and it is not clear which should be given most emphasis.
4. “Achievable robust performance.” This may be viewed as a more detailed version of input-output controllability, where several relevant issues are combined into a single measure. However, this requires that the control problem can actually be formulated clearly, which may be very difficult, as already mentioned. In addition, it requires finding the optimal robust controller for the given problem, which may be very difficult.

Most of these methods are useful for analyzing a given structure (u_2, y_2) but less suitable for selection. Also, the list of methods is also incomplete, as disturbance rejection, which is probably the most important issue for the regulatory layer, is hardly considered.

A Systematic Approach for IO-Selection Based on Minimizing State Drift Caused by Disturbances

The objectives of the regulatory control layer are many, and Yelchuru and Skogestad (2013) list 13 partly conflicting objectives. To have a truly systematic approach to regulatory control design, including IO-selection, we would need to quantify all these partially conflicting objectives in terms of a scalar cost function J_2 . We here

consider a fairly general cost function,

$$J_2 = ||Wx||$$

which may be interpreted as the weighted state drift. One justification for considering the state drift, is that the regulatory layer should ensure that the system, as measured by the weighted states Wx , does not drift too far away from the desired state, and thus stays in the “linear region” when there are disturbances. Note that the cost J_2 is used to *select* controlled variables (CV_2) and not to design the controller (for which the cost may be the control error, $J_2' = ||CV_2 - CV_{2s}||$).

Within this framework, the IO-selection problem for the regulatory layer is then to select the nonsquare matrix H_2 ,

$$CV_2 = H_2 y$$

where $y = [y_m; u]$, such that the cost J_2 is minimized. The cause for changes in J_2 are disturbances d , and we consider the linear model (in deviation variables)

$$\begin{aligned} y &= G^y u + G_d^y d \\ x &= G^x u + G_d^x d \end{aligned}$$

where the G -matrices are transfer matrices. Here, G_d^x gives the effect of the disturbances on the states with no control, and the idea is to reduce the disturbance effect by closing the regulatory control loops. Within the “slow” time scale of the supervisory layer, we can assume that CV_2 is perfectly controlled and thus constant, or $CV_2 = 0$ in terms of deviation variables. This gives

$$CV_2 = H_2 G^y u + H_2 G_d^y d = 0$$

and solving with respect to u gives

$$u = - (H_2 G^y)^{-1} (H_2 G_d^y) d$$

and we have

$$x = P_d^x (H_2) d$$

where

$$P_d^x(H_2) = G_d^x - G^x (H_2 G^y)^{-1} H_2 G_d^y$$

is the disturbance effect for the “partially” controlled system with only the regulatory loops closed. Note that it is not generally possible to make $P_d^x = 0$ because we have more states than we have available inputs. To have a small “state drift,” we want $J_2 = \|W P_d d\|$ to be small, and to have a simple regulatory control system we want to close as few regulatory loops as possible. Assume that we have normalized the disturbances so that the norm of d is 1, then we can solve the following problem

For $0, 1, 2, \dots$ etc. loops closed solve:
 $\min_{H_2} \|M_2(H_2)\|$

where $M_2 = W P_d^x$ and $\dim(u_2) = \dim(y_2) =$
 no. of loops closed.

By comparing the value of $\|M_2(H_2)\|$ with different number of loops closed (i.e., with different H_2), we can then decide on an appropriate regulatory layer structure. For example, assume that we find that the value of J_2 is 110 (0 loops closed), 0.2 (1 loop), and 0.02 (2 loops), and assume we have scaled the disturbances and states such that a J_2 -value less than about 1 is acceptable, then closing 1 regulatory loop is probably the best choice.

In principle, this is straightforward, but there are three remaining *issues*: (1) We need to choose an appropriate norm, (2) we should include measurement noise to avoid selecting insensitive measurements and (3) the problem must be solvable numerically.

Issue 1. The norm of M_2 should be evaluated in the frequency range between the “slow” bandwidth of the supervisory control layer (ω_{B1}) and the “fast” bandwidth of the regulatory control layer (ω_{B2}). However, since it is likely that the system sometimes operates without the supervisory layer, it is reasonable to evaluate the norm of P_d^x in the frequency range from 0 (steady state) to ω_{B2} . Since we want H_2 to be a constant (not frequency-dependent) matrix, it is reasonable to choose H_2 to minimize the norm of M_2 at the frequency where $\|M_2\|$ is expected to have its peak. For some mechanical systems, this may

be at some resonance frequency, but for process control applications it is usually at steady state ($\omega = 0$), that is, we can use the steady-state gain matrices when computing P_d^x . In terms of the norm, we use the 2-norm (Frobenius norm), mainly because it has good numerical properties, and also because it has the interpretation of giving the expected variance in x for normally distributed disturbances.

Issues 2 and 3. If we include also measurement noise n^y , which we should, then the expected value of J_2 is minimized by solving the problem $\min_{H_2} \|M_2(H_2)\|_2$ where (Yelchuru and Skogestad 2013)

$$M_2(H_2) = J_{2uu}^{1/2} (H_2 G^y)^{-1} H_2 Y_2$$

$$\begin{aligned} Y_2 &= [F_2 W_d \ W_n]; \quad F_2 = \frac{\partial y_{\text{opt}}}{\partial d} \\ &= G^y J_{2uu}^{-1} J_{2ud} - G_{dy} \end{aligned}$$

where $J_{2uu} \triangleq \frac{\partial^2 J_2}{\partial u^2} = 2G^{xT} W^T W G^x$, $J_{2ud} \triangleq \frac{\partial^2 J_2}{\partial u \partial d} = 2G^{xT} W^T W G_{dx}$,

Note that this is the same mathematical problem as the “exact local method” presented for selecting $CV_1 = H_1 y$ for minimizing the economic cost J , but because of the specific simple form for the cost J_2 , it is possible to obtain analytical formulas for the optimal sensitivity, F_2 . Again, W_d and W_{ny} are diagonal matrices, expressing the expected magnitude of the disturbances (d) and noise (for y).

For the case when H_2 is a “full” matrix, this can be reformulated as a convex optimization problem and an explicit solution is

$$H_2^T = (Y_2 Y_2^T)^{-1} G^y (G^y)^T (Y_2 Y_2^T)^{-1} G^y)^{-1} J_{2uu}^{1/2}$$

and from this we can find the optimal value of J_2 . It may seem restrictive to assume that H_2 is a “full” matrix, because we usually want to control individual measurements, and then H_2 should be a selection matrix, with 1’s and 0’s. Fortunately, since we in this case want to control as many measurements (y_2) as inputs (u_2), we have that H_2 is square in the selected set, and the opti-

mal value of J_2 when H_2 is a selection matrix is the same as when H_2 is a full matrix. The reason for this is that specifying (controlling) any linear combination of y_2 , uniquely determines the individual y_2 's, since $\dim(u_2) = \dim(y_2)$. Thus, we can find the optimal selection matrix H_2 , by searching through all the candidate square sets of y . This can be effectively solved using the branch and bound approach of Kariwala and Cao, or alternatively it can be solved as a mixed-integer problem with a quadratic program (QP) at each node (Yelchuru and Skogestad 2012). The approach of Yelchuru and Skogestad can also be applied to the case where we allow for disjunct sets of measurement combinations, which may give a lower J_2 in some cases.

Comments on the state drift approach.

1. We have assumed that we perfectly control y_2 using u_2 , at least within the bandwidth of the regulatory control system. Once one has found a candidate control structure (H_2), one should check that it is possible to achieve acceptable control. This may be done by analyzing the input-output controllability of the system $y_2 = G_2 u_2 + G_{2d} d$, based on the transfer matrices $G_2 = H_2 G^y$ and $G_{2d} = H_2 G_d^y$. If the controllability of this system is not acceptable, then one should consider the second-best matrix H_2 (with the second-best value of the state drift J_2) and so on.
2. The state drift cost drift $J_2 = ||Wx||$ is in principle independent of the economic cost (J). This is an advantage because we know that the economically optimal operation (e.g., active constraints) may change, whereas we would like the regulatory layer to remain unchanged. However, it is also a disadvantage, because the regulatory layer determines the initial response to disturbances, and we would like this initial response to be in the right direction economically, so that the required correction from the slower supervisory layer is as small as possible. Actually, this issue can be included by extending the state vector x to include also the economic controlled variables, CV_1 , which is selected based on the economic cost J . The weight matrix W may then be used to adjust the relative weights of avoiding drift in the internal states x and economic controlled variables CV_1 .
3. The above steady-state approach does not consider input-output pairing, for which dynamics are usually the main issue. The main pairing rule is to “pair close” in order to minimize the effective time delay between the selected input and output. For a more detailed approach, decentralized input-output controllability must be considered.

Summary and Future Directions

Control structure design involves the structural decisions that must be made before designing the actual controller, and it is in most cases a much more important step than the controller design. In spite of this, the theoretical tools for making the structural decisions are much less developed than for controller design. This chapter summarizes some approaches, and it is expected, or at least hoped, that this important area will further develop in the years to come.

The most important structural decision is usually related to selecting the economic controlled variables, $CV_1 = H_1 y$, and the stabilizing controlled variables, $CV_2 = H_2 y$. However, control engineers have traditionally not used the degrees of freedom in the matrices H_1 and H_2 , and this chapter has summarized some approaches.

There has been a belief that the use of “advanced control,” e.g., MPC, makes control structure design less important. However, this is not correct because also for MPC must one choose inputs ($MV_1 = CV_{2s}$) and outputs (CV_1). The selection of CV_1 may to some extent be avoided by use of “Dynamic Real-Time Optimization (DRTO)” or “Economic MPC,” but these optimizing controllers usually operate on a slower time scale by sending setpoints to the basic control layer ($MV_1 = CV_{2s}$), which means that selecting the variables CV_2 is critical for achieving (close to) optimality on the fast time scale.

Control System Optimization Methods in the Frequency Domain

Christina M. Ivler

Shiley School of Engineering, University of Portland, Portland, OR, USA

Abstract

When designing a compensator, there are typically a range of solutions that provide a closed-loop response meeting the design requirements. An optimal solution is one that meets the design specifications while minimizing or maximizing an objective function. The process for formulating control compensator design as an optimization problem is described in this article. An example case is given to illustrate control system optimization methods in the frequency domain.

Keywords

Multi-objective optimization · Specifications · Design parameters · Summed objectives · Pareto-optimal · Crossover frequency · Actuator activity

Introduction

As discussed in ► [“Classical Frequency-Domain Design Methods”](#), classical frequency domain methods can be used for selecting a dynamic compensator $D(s)$ that meets the design requirements for a closed-loop system, illustrated by Fig. 1. The method presented herein is a more sophisticated extension of that, where the goal is to determine an optimum compensator $D(s)$. Minimizing actuator activity of the control system is a common optimization objective. Additionally, minimizing the gain at higher frequencies reduces sensitivity to noise and eliminates unnecessary actuator fatigue. The design specifications are formulated in the fre-

quency domain for ease and speed of evaluation. The control designer selects a compensation structure, (e.g., lead-lag, proportional-integral-derivative), and the associated design parameters to be optimized within the compensator (e.g., lead frequency, proportional gain, integral gain). Then a multi-objective optimization engine, such as CONDUIT[®] in Tischler et al. (2017), can be used to find the optimal settings for those compensator design parameters.

Design Specifications

Of key importance to successful control system design, including design using optimization, is the careful selection of the requirements. When developing the compensator, a set of comprehensive specifications is selected to guide the design. This set prescribes the behavior of the desired system, typically covering desired stability robustness, command tracking, steady-state error, damping ratio, and disturbance rejection capabilities of the system. Frequency-response-based specifications are recommended because of the ease and speed of evaluation and generally linear variation of frequency-response metrics with design parameters. In contrast, time domain specifications require time simulations, which are more computationally expensive to run and evaluate than frequency-response-based specifications. This is especially important for direct optimization methods because many iterations and subsequent evaluations of the specifications are required.

To ensure stability, stable eigenvalue (λ_j) would be selected as a design requirement, $Re(\lambda_j) \leq 0$. Then minimum gain margin (GM) and phase margin (PM), defined in ►“Frequency-Response and Frequency-Domain Models”, are typically specified to ensure sufficient stability robustness such that magnitude and phase variation can be tolerated prior to onset of instability. A key command tracking requirement is bandwidth, ω_{BW} also defined in ►“Frequency-Response and Frequency-Domain

Models”. Bandwidth is a measure of the maximum input frequency for which the system has acceptable tracking and characterizes the speed of the response. The resonant peak, M_r , which is the maximum amplitude of the closed-loop frequency response as in ►“Frequency-Response and Frequency-Domain Models”, is another possible design specification which can be used to characterize allowable overshoot. The allowable steady-state error (e_{ss}) is another common command tracking requirement. A minimum damping ratio ζ for all eigenvalues may also be prescribed to ensure that the system has sufficient damping. If the control designer is concerned with disturbance rejection capabilities, minimum acceptable of disturbance rejection bandwidth ω_{DRB} and maximum allowable disturbance rejection peak M_d , both of which are defined in ►“Frequency-Response and Frequency-Domain Models” may be specified as additional design requirements. Disturbance rejection bandwidth defines the speed of recovery from disturbances, and the disturbance rejection peak describes the overshoot of the disturbance response.

The exact design specifications will vary based on industry best practices and standards, depending on the intended application.

Objective Functions

In the case where multiple compensator solutions meet the set of design specifications, it seems natural to choose a design that is optimal in some way. Actuator usage is often selected as an objective function to minimize, which can provide many benefits:

- Improves stability robustness,
- More efficient energy consumption of the actuators,
- Relieves actuator saturation, which can cause undesirable behavior, such as limit cycles.

Moreover, minimizing high-frequency actuator activity has several additional benefits:

- Reduces likelihood of exciting higher frequency unmodeled dynamics, such as structural modes of the physical system,
- Lessens sensitivity to sensor noise, which typically occurs at higher frequency than the plant dynamics (if the sensor is chosen appropriately).

For the system in Fig. 1, actuator response to a reference input is given by $A(s)$:

$$A(s) = \frac{U(s)}{R(s)} = \frac{D(s)F(s)}{1 + D(s)F(s)G(s)} \quad (1)$$

A metric for the actuator usage is the variance of the actuator response σ_a^2 . In the frequency domain, σ_a^2 due to a white noise input, which excites the system at all frequencies, is proportional to the area under of the square of the magnitude response of $A(s)$ as described in (Tischler et al. 2017):

$$f_{\text{obj}_1} = \int_0^\infty |A(j\omega)|^2 d\omega. \quad (2)$$

Thus by minimizing the objective f_{obj_1} , actuator usage is also minimized. The objective function f_{obj_1} can be visualized as the shaded area under the plot of $|A(s)|^2$, illustrated in Fig. 2a for two different compensators $D_1(s)$ and $D_2(s)$, applied to the same plant $G(s)$. For practicality, the integral is only evaluated over a finite region, as shown in Fig. 2.

By itself f_{obj_1} provides information about the magnitude of the overall actuator usage but not the frequency content of the signal. A second objective is needed to ensure that high-frequency actuator activity is minimized. A recommended f_{obj_2} is the open-loop magnitude 1 (0db) crossover frequency ω_c which characterizes the frequency where the combination of the plant and compensator start to attenuate:

Control System Optimization Methods in the Frequency Domain, Fig. 1 Feedback system showing compensation

Control System Optimization Methods in the Frequency Domain, Fig. 2 (a) Actuator activity in the frequency domain (b) Open-loop crossover frequency

$$D(j\omega_c)F(j\omega_c)G(j\omega_c) = 1 \quad f_{\text{obj}_2} = \omega_c \quad (3) \quad \text{requirement:}$$

In Fig. 2a, it is clear that the total area under the curve cannot capture the differences in the frequency distribution of the actuator activity, which is concentrated at higher frequency in $D_2(s)$. However, the crossover frequency ω_c , which is higher for $D_2(s)$, better captures this effect.

Optimizing for a combination f_{obj_1} and f_{obj_2} ensures that both the overall actuator usage and the frequency of the activity are minimal. A recommended cost function to be minimized is given by:

$$J = \bar{f}_{\text{obj}_1} + \bar{f}_{\text{obj}_2} \quad (4)$$

where $\bar{f}_{\text{obj}_1}$ and $\bar{f}_{\text{obj}_2}$ are normalized (or weighted) versions of f_{obj_1} and f_{obj_2} .

Multi-objective Optimization Formulation

Modern control state-space methods such as LQR, described in Franklin et al. (2019), provide optimal solutions that have stability robustness while minimizing actuator activity. However, there is no direct way to tune weighting matrices that are used in modern control methods (such as Q and R) to simultaneously meet the design requirements for key frequency domain design specifications like bandwidth, peak resonance, disturbance rejection bandwidth, etc. In the case that one or multiple frequency domain design requirements are in place, a direct multi-objective optimization algorithm can be used to find the solution that meets all requirements with minimal actuator activity.

In multi-objective optimization, there are many solvers available and associated methods to frame the problem. A commonly accepted method of formulating an optimization-based control design problem, used by Tischler et al. (2017), is as a weighted sum optimization of the objective functions $\bar{f}_{\text{obj}_i}$ and where the design criteria $\bar{f}_i$ are reformulated so that a value of less than zero indicates compliance with the

$$\begin{aligned} &\text{minimize } J(x) = \sum \bar{f}_{\text{obj}_i}, \\ &\text{subject to : } \bar{f}_i(x) \leq 0, x_{\min} \leq x \leq x_{\max} \end{aligned} \quad (5)$$

The summed objective $J(x)$ to be minimized is a sum of the normalized objective functions. The unknown quantities to determine, x , are the compensator elements to be optimized, for example, the gain and pole/zero locations of a lead compensator. The objective functions are normalized so that they are expressed in equivalent units and to ensure that each individual objective is appropriately weighted in the optimization. A recommended method is to normalize each objective in units of relative “goodness”:

$$\bar{f}_{\text{obj}_i} = \frac{f_{\text{obj}_i} - f_{\text{obj}_{i\text{good}}}}{f_{\text{obj}_{i\text{bad}}} - f_{\text{obj}_{i\text{good}}}}. \quad (6)$$

A comprehensive set of system characteristics f_i are selected with associated design requirements $f_{i\text{good}}$ and $f_{i\text{bad}}$. After these are determined, then the normalized design specifications can be formulated similarly to the design objectives:

$$\bar{f}_i = \frac{f_i - f_{i\text{good}}}{f_{i\text{bad}} - f_{i\text{good}}}, \quad (7)$$

such that $\bar{f}_i = 0$ when the design characteristic is exactly equal to the design requirement $f_{i\text{good}}$. Any values $\bar{f}_i(x) \leq 0$ indicate that design requirement has been achieved. This methodology is used in the CONDUIT[®] software as described by Tischler et al. (2017). It is an important step that ensures all design specifications are equally weighted by their good and bad values so that all the design constraints are in the same normalized unit system. This provides a more balanced design space and better posed optimization.

The optimization concept can be visualized by Fig. 3, which illustrates the concepts of feasible design space, Pareto-optimal front and optimal solution. The feasible design space indicates where there are solutions for x that meet all the design requirements. The optimal point is

Control System Optimization Methods in the Frequency Domain, Fig. 3

Illustration of optimization design space and Pareto-optimal front

where the sum of both objective functions is smallest. The black line represents the Pareto-optimal front, which shows optimal solutions if there was a different weighting of the objective functions. For example, if it was desirable to further reduce (improve) f_{obj1} , the Pareto-optimal trade-off is achieved at the cost of larger (worse) f_{obj2} .

Optimization Process

In the approach presented by Tischler et al. (2017), and integrated into the CONDUIT[®] software, a three-tiered optimization approach is employed. All design specifications are broken into three categories:

- Hard requirements: all design specifications associated with stability,
- Soft requirements: all design specifications that are associated with performance,
- Objective requirements: all design specifications included in the objective function.

The optimization is also split into three Phases:

- Phase 1: The optimization engine first works toward meeting all the hard requirements, while ignoring the soft and objective requirements. This moves the solution into a stable, reasonable design space,
- Phase 2: All soft requirements are optimized to meet the design specification, while still enforcing the hard requirements,

- Phase 3: When a feasible design that meets all hard and soft requirements is achieved, the optimization will then minimize the objective functions within the feasible design space.

As described by Tischler et al. (2017), a robust methodology for control system optimization is achieved with this phased approach. This method guides the optimization toward the feasible design space prior to optimizing the objective cost function. It is not useful to minimize the objectives if the design requirements are not met, as they represent the necessary performance needed for the system to behave satisfactorily. In the case that the design is not feasible or the minimum cost function is still too high after optimization, the design requirements can be relaxed.

Example Case

To illustrate the concept and advantages of direct multi-objective optimization for design of a dynamic compensator $D(s)$, a simple design example is presented for the block diagram in Fig. 1. For this example case, the dynamics of the system to be controlled $G(s)$ can be represented by the following transfer function model:

$$G(s) = \frac{0.2(s + 0.5)}{(s + 3)(s + 0.1)}, \quad (8)$$

That has associated actuator dynamics:

$$F(s) = \frac{20}{s + 20}, \quad (9)$$

And assuming the control designer has selected a compensator of the following form, which is effectively a proportional-integral type control system:

$$D(s) = \frac{k(s+a)}{s}, \quad (10)$$

The resulting closed-loop response $T(s)$ and actuator response $A(s)$ are:

$$T(s) = \frac{G(s)F(s)D(s)}{1 + G(s)F(s)D(s)}, \quad (11)$$

$$A(s) = \frac{G(s)F(s)}{1 + G(s)F(s)D(s)}. \quad (12)$$

The design parameters x of the compensator to be selected via optimization are:

- The gain k ,
- The zero location $-a$.

The design specifications and classifications (hard requirement, soft requirement, and objective function) are:

- Stability specifications (Hard requirements): $\text{real}(\lambda_i) \leq 0$, $GM \geq 6$ db, $PM \geq 45$ deg
- Command tracking specifications (Soft requirements): $\omega_{BW} \geq 1.5$ rad/s, $M_r \leq 1$ db, $e_{ss} \leq 5\%$ (step input)

- Disturbance specifications (Soft requirements): $\omega_{DRB} \geq 0.7$ rad/s, $M_d \leq 5$ db
- Summed objective functions: $f_{obj1} = \int_{0.01}^{1000} |A(s)|^2 d\omega$, $f_{obj2} = \omega_c$.

The feasible design space for this problem can be visualized by the chart shown in Fig. 4, which was identified via discrete perturbation of the design parameters and associated mapping of the design space. Due to the low number of design parameters, this is possible for demonstration purposes, but is not as efficient as an optimization engine such as CONDUIT®. This plot shows the optimal solution with an asterisk, and also the Pareto-optimal front which is highlighted in black. Along this Pareto-optimal front, trade-off of increasing crossover frequency, associated with increased performance (higher bandwidth, rise time, etc.), can be achieved at the cost of increased actuator activity. In Region 1 of the Pareto-optimal front, as labeled in Fig. 4, it can be seen that increased performance is achieved with relatively little change in actuator activity. In contrast, further increases in crossover frequency into Region 2 come with a much larger associated cost in actuator activity. The control designer might choose to take advantage of a higher performing design from Region 1 of the Pareto front, so that some design margin is present above the minimum required performance at the cost of slight increase in actuator activity.

Control System Optimization Methods in the Frequency Domain, Fig. 4 Feasible design space, and optimal solution for example case
 $G(s) = \frac{0.2(s+0.5)}{(s+3)(s+0.1)}$

Control System Optimization Methods in the Frequency Domain, Fig. 5 Feasible design parameter combinations and optimal design point

Control System Optimization Methods in the Frequency Domain, Fig. 6 Optimal and feasible design performance for example case

The optimal design point is shown relative to all feasible values of the design parameters (a , k) in Fig. 5. A comparison of the optimal point with two other feasible, but non-optimal, designs from Fig. 5 was performed. The two non-optimal design points selected in Fig. 5 are shown with circle markers, and the optimal design point with an asterisk. Figure 6 shows key design features for each of these three designs from Fig. 5. While all three designs meet the design specifications, it is clear from Fig. 6a that the optimal design

has reduced actuator activity and has less high-frequency content than the other designs. The time-domain performance of the optimal closed-loop response is slightly slower (associated with lower bandwidth) than the non-optimal solutions because the optimal solution provides the minimum performance needed to just meet the design requirement, as this solution provides minimum actuator usage. The time-history response of the actuator confirms that its usage is reduced for the optimal design, as expected.

Summary and Future Directions

Control system optimization is a method for determining a dynamic compensator design that meets all the specifications with minimum actuator activity. The selection of the design specifications, classification of the specifications, and objective functions significantly affect the optimal solution. These should be carefully selected according to industry standards for the application at hand.

Switzerland

Abstract

An essential role in nanotechnology applications is played by nanopositioning control systems, which allow nanometer-scale precision and accuracy at dimensions of tens of nanometers or less. Nanopositioners are precision mechatronics systems aiming at moving or identifying objects over a certain

distance with a resolution of the order of a nanometer. In nanopositioners, actuation, position sensing, and feedback control are the key components that determine how successfully the stringent requirements on resolution, accuracy, stability, and bandwidth are achieved. Historically, nanopositioning found its earlier applications in scanning probe microscopy. Today it turns out to be increasingly important for lithography tools, semiconductor inspection systems, molecular biology, metrology, nanofabrication, and nanomanufacturing. Moreover, nanopositioning control represents a fundamental requirement in storage systems ranging from probe-based storage devices to mechatronic tape drive systems to achieve ultrahigh areal density and storage capacity.

Keywords

Scanning probe microscopy · Feedback control systems · Robust control · Data storage systems · Nanolithography

Introduction

The past three decades have witnessed the emergence and explosive growth of nanoscience and nanotechnology, which significantly advanced our understanding and control of physical processes on the nanometer and subnanometer scale. Nanopositioning control systems are at the core of this revolution. Nanopositioners may be viewed as precision mechatronics systems that are capable of positioning of samples with a resolution that could be as high as a fraction of a nanometer to enable interrogation and modification of the sample surface. The early applications were found in scanning probe microscopy (Salapaka et al. 2002; Devasia et al. 2007). Moving or identifying objects with a scanning probe microscope (SPM) requires positioning systems with atomic-scale resolution. SPM is one of the most important tools in nanoscale science and engineering. For example, SPM has enabled the visualization of individual atoms and even of chemical bonds between

atoms in a single molecule. More recently, nanopositioning systems have become key elements of novel lithography tools that represent an alternative to optical lithography systems (Oomen et al. 2014). During the production process of integrated circuits, a wafer scanner system must track a predefined reference trajectory with extreme accuracy in six motion degrees of freedom (DOFs) for mask alignment and semiconductor inspection. Furthermore, nanopositioning systems are essential for imaging, alignment, and nanomanipulation as required, for example, in molecular biology for cell tracking and DNA analysis (Ando et al. 2007) and in metrology, nanoassembly, and nanomanufacturing applications. Finally, they are also essential for data storage devices where accurate positioning of write/read elements is required to achieve ultrahigh areal density and near-optimum capacity, such as hard disk drives (HDDs), tape drives, and optical drives (Cherubini et al. 2012). For example, nanometer-scale precision was demonstrated in probe storage devices with areal densities of multi-terabit per square inch (Tbit/in²) (Sebastian et al. 2008). The extensive range of applications with operation under vastly diverse conditions poses significant challenges for the control of nanopositioning devices, as they necessitate high resolution, high bandwidth, and robust control designs.

Nanopositioning for Scanning Probe Microscopy

Figure 1 depicts a typical SPM device, where the sample under investigation is positioned relative to an atomically sharp probe tip mounted on a micromechanical cantilever spring that interacts with the sample (Tuma et al. 2013). A feedback loop provides the required accuracy and precision for lateral nanopositioning of an electromechanical device, known as nanopositioner or scanner. Vertical nanopositioning, not depicted in the figure, regulates the force between the tip and the sample (Sebastian et al. 2003). Actuation and sensing objectives are significantly different for the lateral and vertical positioners. Therefore, lateral and vertical nanopositioning are usually decoupled. An example of vertical nanopositioning system is the self-tuning proportional-integral (PI) control system (Tajaddodianfar et al. 2018) introduced to improve the robustness of scanning tunneling microscopes (STMs) against tip crashing into the sample surface, while patterning the surface with a resolution down to a single atom through lithography or subsequent imaging. It turns out that the stability of the STM vertical control system is affected by variations in the local tunnel barrier height, a local quantum mechanical property that depends on the physical properties of the tip apex and of those of the sample surface atoms

Control Systems for Nanopositioning,

Fig. 1 Lateral nanopositioning in SPM

into which the current tunnels. In the remaining part of this section, however, we will focus on lateral nanopositioning. The primary objective in lateral nanopositioning is to make the scanner follow, or track, a given reference trajectory by an appropriate control method, which may rely on feedforward control, feedback control, or combinations thereof. Over the wide bandwidths of the order of 10 kHz or more required by applications at high scanner speeds, the model uncertainties, mechanical cross-coupling, and actuation noise cannot be considered negligible. Hence feedforward control alone is not adequate, and feedback control is essential to achieve nanoscale accuracy and precision at high speeds. A feedback controller, denoted by K in Fig. 1, is used to control the scanner position in the two x and y dimensions, with the objective to follow a predetermined (r_x, r_y) reference trajectory, relying on the positional information provided by a position sensor. The tracking error includes both deterministic and stochastic components, which mainly affect the positioning accuracy and the precision, respectively. Deterministic tracking errors are mostly originated by an insufficient closed-loop bandwidth, mechanical resonant scanner modes, and actuator nonlinearities, e.g., hysteresis. Stochastic tracking errors are typically originated by external vibrations and noise, actuator noise, and position-sensing noise. To minimize both the deterministic and the stochastic tracking error components, it is therefore essential to simultaneously improve the position sensor, the scanning device, the feedback controller, and the reference trajectory.

Low-Noise Sensing

The amount of noise in the position measurement signal determines the sensor resolution over a given bandwidth, which in turn determines the resolution achievable in the nanopositioning feedback system. The resolution is usually characterized in terms of the standard deviation of the sensing noise with the scanner at rest. The resolution therefore deteriorates as the sensing bandwidth increases. The actuator noise can be minimized by carefully designing the drive circuitry. With increasing feedback bandwidth,

however, the sensing noise may enter the feedback loop introducing random positioning errors and adversely affect the positioning precision. The amount of scanner motion induced by the measurement noise may be comparable to the dimensions of the nanoscale structures that are to be resolved. For example, the sensing noise-induced scanner motion may amount to several nanometers over a bandwidth of 10 kHz. The measurement noise can be decreased by using advanced low-noise sensing concepts. Some widely used position sensors that attain nanometer- or subnanometer-scale resolution include capacitive, piezoresistive, optical, and magnetoresistive sensors.

Scanners

Scanner properties eventually determine the achievable performance of a nanopositioning system, the control architectures, the sensing scheme, and the scan trajectories that can be used. An SPM scanner usually must satisfy three requirements: (1) a linear relationship between the actuation signal and the scan table position, with well-defined dynamic behavior; (2) a large range of motion of at least tens to hundreds of micrometers for a variety of applications; and (3) a flat dynamic response over a wide bandwidth to ensure low sensitivity of closed-loop performance to variations in the scanner dynamics and to enable efficient control designs that provide low sensitivity to sensing noise. Most SPM scanners are based on piezoelectric actuation, because of the achievable large bandwidth, robustness, and large actuation force. Tube-based piezoelectric scanners are not expensive and are easy to design and use. However, they are not well suited for high-speed applications due to the relatively high amount of cross-coupling between the positioning axes and the low resonant frequencies. An alternative approach is provided by flexure-guided scanners actuated by piezoelectric stack actuators, where the sample is displaced by elastic deformation of a flexible structure (flexure) that guides the scan table. The main disadvantage of piezoelectric actuators is that they exhibit nonlinear characteristics, to be ascribed to hysteresis, creep, and drift. To

compensate for these nonlinearities, broadband feedback control is typically required, which may negatively affect the closed-loop positioning resolution. Compared to piezoelectric actuators, the dynamics of electromagnetic and electrostatic actuators are much more linear. A disadvantage of electromagnetic and electrostatic actuation, however, is the low actuation force, which limits the achievable range of motion in stiff scanners such as high bandwidth flexure-guided scanners. An elegant approach to decouple the requirements of having a high resonant frequency and a large range is provided by dual-stage positioning, as applied, for example, in optical and magnetic recording. A dual-stage nanopositioner usually comprises a slow, large-range scanner linked in series with a short-range scanner optimized for high speed. In this system, more challenging requirements are imposed on the high-speed scanner. In SPM, only one axis typically requires high-speed actuation, in which case the short-range scanner can be designed solely for uniaxial actuation to allow a clean dynamic response and low interaxial crosstalk. For scanning in other scan directions, as well as scanning over a large area, the large-range scanner is used.

Feedback Control

A suitable feedback control architecture is characterized by good tracking and disturbance rejection performance, while being insensitive to the position-sensing noise. A further requirement is the robustness of the controller to variations in the system mechanical properties. Figure 2 shows three feedback control techniques commonly applied in nanopositioning. Figure 2a depicts the conventional proportional-integral-derivative (PID) feedback control technique for the x positioning axis, where the controller, K_x , includes the proportional, integral, and derivative terms. The controller input is given by the position error signal, e_x , obtained by subtracting the noisy position measurement, $x + n_x$, where the position measurement signal and additive measurement noise are denoted by x and n_x , respectively, from the reference signal, r_x . The performance of PID control is limited in terms

of achieving a high closed-loop bandwidth and robustness to plant uncertainties, which make PID controllers less suitable for high-speed nanopositioning systems in spite of the popularity of the method. Figure 2b shows a 1-DOF feedback control technique, where the feedback controller, K_x , is assumed to be a single-input, single-output dynamical system specifically designed for a given closed-loop performance. In nanopositioning, robust control design methods, such as the H_∞ approach, in which the controller is obtained by mathematical optimization, have been shown to extend the closed-loop bandwidth significantly while maintaining robust performance. However, with 1-DOF controllers, achieving a good tracking performance in the presence of significant sensing noise remains a challenging problem because of inherent limitations such as the waterbed effect. This issue can be overcome by a 2-DOF controller, as depicted in Fig. 2c. In 2-DOF control, the feedback component and the feedforward component of the controller are decoupled. Using this approach, the reference tracking transfer function, from r_x to x , can be designed independently of the noise sensitivity transfer function, from n_x to x . A very high positioning precision can be achieved by designing the controller to carefully shape the closed-loop noise sensitivity transfer function. In applications where the reference signal is of repetitive nature, specialized nonlinear control methods such as adaptive control, repetitive control, and iterative learning control can be used. Advanced control architectures for noise-resilient nanopositioning have been proposed that combine some of the above-mentioned methods, e.g., combining robust control design and shaping of the noise sensitivity transfer function.

Scan Trajectories

The scan trajectory determines the reference signals that must be tracked by the nanopositioner. Therefore, it has a significant impact on the choice of the control technique, the achievable tracking performance, and the sensitivity of the closed-loop system to sensing noise. Figure 3 shows the scan trajectory and image

Control Systems for Nanopositioning, Fig. 3 Scan trajectory and image reconstruction in SPM nanopositioning

reconstruction concepts for a nanopositioning system. The scan trajectory reference signals $r_x(t)$ and $r_y(t)$ to be tracked by the nanopositioning system are determined for the required scan duration and spatial resolution. Tracking is usually achieved by a feedback loop relying

on measurements of the x and the y scanner position. At each position $x(t)$, $y(t)$, a measure of a local surface property referred to as scan data, e.g., the topography, is obtained. For almost all nanopositioning applications, a scan trajectory is provided to systematically traverse

a two-dimensional sample surface to enable imaging and/or manipulation of the sample. A raster scan trajectory is conventionally adopted, which scans the sample in consecutive lines by actuating the scanner with a triangular waveform in one axis and by shifting the sample position in steps or continuously in the orthogonal axis. The raster scan trajectory continues to be the most widely used scan trajectory for both industrial and scientific instruments, mostly because of the simplicity of the image reconstruction. However, with increasing scan speeds, the high-frequency components of the trajectory reference signals excite the mechanical resonant modes of the nanopositioner and introduce unwanted residual vibrations and tracking errors. These high-frequency components come from the sharp turnaround points of the raster scan trajectory and result in a wide spectrum of frequencies of the reference signal, requiring broadband feedback compensation and hence deteriorating the noise resilience of the system. For this reason, the frequency spectrum is often shaped by smoothening the turnaround points. More recently, alternative scan patterns have been proposed that cover the sample area with a desired resolution but at the same time require only reference signals with a narrowband frequency spectrum, e.g., spiral scanning, where

the reference signals are sinusoidal waveforms of varying frequency and/or amplitude.

Nanopositioning for Probe-Based Data Storage

Subnanometer precision at fast rates is required in a wide range of applications, including probe-based data storage (Eleftheriou et al. 2003). Probe-based data storage is an alternative to magnetic storage that has been proposed for both mobile and archival applications because of its ultrahigh areal density, which can achieve several Tbit/in². Among the various probe-based data storage concepts, thermomechanical recording and retrieval of data encoded as nanometer-scale indentations in thin polymer films was the first to be demonstrated in a fully functional probe-based storage device. A schematic illustrating a probe-based storage device and a photograph of a miniaturized device prototype are shown in Fig. 4 (Sebastian et al. 2008). An array of thermomechanical probes is used to read and write information. The data are recorded as indentations on a thin polymer film, which acts as the storage medium. In data storage applications, high bandwidth and high-resolution nanopositioning are essential. This dual objective requires the

Control Systems for Nanopositioning, Fig. 4 Scanning probe-based storage device: (a) diagram of the storage device comprising the two-dimensional microcantilever

array chip and the storage medium on a MEMS microscanner; (b) photograph of the probe-based storage device prototype

design and development of adequate sensors and actuators as well as suitable control strategies. The positioning system for the scanning probe-based data storage device prototype consists primarily of an electromechanical microscanner that positions the storage medium relative to the cantilever array, thermal position sensors that provide global position information, and servo fields that generate medium-derived position information. Unlike typical SPM nanopositioning applications, which require relative positioning, data storage devices require absolute positioning. Moreover, this absolute positioning needs to be provided across the entire area of the storage field with nanometer-scale precision. Hence, position information must be inscribed on the medium. In the probe storage device prototype, certain storage fields, known as servo fields, and the associated microcantilevers are therefore reserved for the generation of position information. Prewritten servo patterns in the servo fields provide the needed alternative position signal. This signal measures the deviation of the microcantilever tip from the track center during the read/write operation. The medium-derived position error signal (PES) is based on sequences of indentations, which are mutually displaced along the orthogonal direction to the scan direction, arranged in such a way as to produce two signals in quadrature, which can be combined to provide a PES. During regular operation of the device, the nanopositioning system, referred to as the servo system, has two main functions. First, from an arbitrary initial position of the scan table, the target track for read/write operations must be located, which is achieved by the seek-and-settle procedure. Typical worst-case seek times are of the order of 1 ms. The second function of the servo system is to maintain the position of the read/write probes on the center of the target track during the scanning process along the length of this track, which is achieved by the track-follow procedure. During track-follow, each track is scanned in the horizontal direction with constant velocity, while maintaining the fine positioning in the cross-track direction in the presence of disturbances and noise. For probe-based data storage, where the data rate per probe

is relatively low, a linear scan velocity of a few millimeters per second is typically considered. Hence, the requirement on tracking bandwidth is rather modest. In contrast, disturbance rejection is required, but its extent depends on the application. In mobile applications, for example, it is necessary to have good disturbance rejection capability up to about 500 Hz. The higher the requirement on disturbance rejection, the higher the sensitivity of the system to measurement noise. This fundamental trade-off needs to be addressed when designing controllers for probe-based storage devices.

Nanoscale Track-Following in Tape Drives

The volume of digital data produced each year is growing at an ever-increasing pace. Moreover, new regulatory requirements imply that a larger fraction of this data will have to be preserved. All of this translates into a growing need for cost-effective digital archives. State-of-the-art linear tape products found on the market achieve an areal storage density of about 10 Gbit/in² and a cartridge capacity of about 20 terabytes. Future scaling will require a dramatic increase in track density and hence the improvement of the positioning accuracy of the read/write heads at the nanoscale. A single-channel tape areal density of 201 Gbit/in² on a prototype sputtered magnetic tape medium has been recently demonstrated, which would correspond to a cartridge capacity of about 330 terabytes (Furrer et al. 2018a). The lateral position of the head is derived from the relative timing of bursts of pulses in the servo readback waveforms, which are obtained by reading servo patterns that are written on the tape with opposite or identical azimuth angles. A closed-loop control system has the task of following with high accuracy the lateral tape motion (LTM) while attenuating effects from noise in the position measurement. These conflicting requirements can be systematically addressed using the H_∞ control framework. Figure 5 depicts a schematic diagram of the H_∞ control formulation for the track-following

Control Systems for Nanopositioning, Fig. 5 Block diagram of the H_∞ control formulation for the track-following controller design

controller design (Pantazi et al. 2015; Furrer et al. 2018b). The lateral dynamics of the head actuator are described by the transfer function G . The transfer function is dominated by a main actuator resonance at a frequency of about 100 Hz and is captured well by a second-order model. The input to the controller, K , is the PES, e , that measures the difference between the target track location on the tape and the estimated head position in the lateral direction. In addition to measurement noise effects, the PES is affected by the estimation delay, captured by D , which is a function of the tape speed v_{tape} . As the tape speed is increased, the servo pattern delay is reduced while at the same time the LTM disturbances, denoted by d_{LTM} , shift to higher frequencies. Because of the speed dependence of both the delay and the frequency characteristics of the lateral tape motion, a set of track-following controllers are designed, with each controller optimized for a given tape speed. Specifically, for each tape speed, the weighting transfer functions W_s and W_u are adapted to capture the control objectives for the LTM disturbance rejection and for limiting the control effort, respectively. For the tape areal density demonstration of 201 Gbit/in², a standard deviation of the PES of less than 6.5 nm was achieved over the speed range of 1.2–4.1 m/s, corresponding to

the full speed range of a typical commercial tape drive.

Summary and Future Directions

The demand for video-rate SPM will increase, particularly in fields that involve the investigation of biological specimens, high-throughput nanomachining, and nanofabrication. Therefore, approaches to improve the scan speed of the SPM, for example, by employing non-raster scan methods, are likely to gain increased use. In this context, internal model controllers, which include the dynamic modes of the reference and disturbance signals in the feedback controller while preserving system stability, can provide adequate tracking and robust performance without imposing a high control bandwidth. The study of the non-linear dynamics of the vertical positioning systems will motivate the development of advanced control systems to detect the distance from the SPM cantilever tip to the sample substrate in a more robust manner. High-density storage technologies based on scanning probe devices will continue to be investigated. Besides the thermomechanical data storage approach discussed earlier, ferroelectric and phase change materials are candidates for next-generation high-density SPM

data storage technologies. Advanced positioning control methods are also envisaged to improve the density of recording in data storage systems, for example, to achieve densities of the order of a few Tbit/in² in HDDs and capacities of the order of a few hundreds of terabytes in tape systems.

Control-Based Segmentation

Liangjia Zhu, Ivan Kolesov, Peter Karasev, and Allen Tannenbaum

Department of Computer Science, Stony Brook University, Stony Brook, NY, USA

Abstract

Image segmentation is a fundamental problem in image processing, computer vision, and medical imaging applications. The design of generic, automated methods that work for various objects and imaging modalities is a daunting task. Instead of proposing new specific segmentation algorithms, in this entry, we review a general design principle on how to integrate user interactions from the perspective of feedback control theory. In particular, impulsive control and Lyapunov stability analysis are employed to design and analyze an interactive segmentation system. Stabilization conditions are derived to guide algorithm design. The effectiveness and robustness of the proposed methodologies are demonstrated.

Segmentation · Active contours · Feedback · Observers

Introduction

Given the variability of real-world imagery, one many times needs to supplement the given automatic algorithm with some human interaction, which brings in the entire subject of how this interaction should take place. We propose to use techniques from feedback control for this purpose making use of the ideas elucidated in Karasev et al. (2013) and Zhu et al. (2018). Thus, we study steerable segmentation from a closed-loop perspective. We desire an interactive system to enable a user to create excellent segmentation results with a minimal amount of time and effort. With the rich resources from control theory, we can quantitatively design and evaluate the performance of a control-based segmentation system. Figure 1 sketches the proposed interactive segmentation framework.

The literature for segmentation is much too huge to survey here. The bottom line is that automated segmentation methods have never been widely adopted in real-world settings, such as in the clinic. As a result, users directly participate in the segmentation loop in various image segmentation systems. This body of methods is called *interactive segmentation* (Boykov and Funka-Lea 2006; Vezhnevets and Konouchine 2005). Typically, the user begins initializing the given algorithm and then iteratively modifies the intermediate results until one obtains a satisfactory result. This process may be viewed as a feedback control process, whereby the user's editing action is a controller, the visualization/monitoring is an observer, and the changes of the intermediate results drive the system dynamics. In this sense, the user automatically fills in the "information" gap between an imperfect model to that of a desired segmentation result. However, most of the work along these lines does not explicitly model the user's role from a systems and control point of view. More precisely, user inputs are utilized *passively* without consideration to their contribution to the stability or convergence of the overall system. To the best of our knowledge, there are very few attempts to model segmentation from the perspective of feedback control. The work of Karasev et al. (2013) and Zhu et al. (2018)

precisely considers this task and is summarized in the present entry.

Open-Loop Automatic Segmentation

A large class of segmentation algorithms may be considered as dynamic processes. Starting from a given region, these approaches evolve the region based on certain segmentation criteria. Examples include region growing/competition, classical active contour models, and distance-based segmentation. Typically, the dynamic process can be described by a differential/difference equation, driven by the optimization of certain energy function(al)s. Active contours implemented via level sets are a key example (Osher and Fedkiw 2003).

Let $I : \Lambda \rightarrow \mathbb{R}^m$ be an image defined on $\Lambda \subset \mathbb{R}^n$, where $m \geq 1$ and $n \geq 2$. Suppose an image to be segmented consists of N regions. Each region $\Lambda_i(\mathbf{x}, t)$ is associated with a level set function $\psi_i(\mathbf{x}, t)$ and is evolving from an initial state $\psi_i(\mathbf{x}, 0) = \psi_i^0(\mathbf{x})$ with $\{\mathbf{x} | \psi_i^0(\mathbf{x}) = 0\} = \partial \Lambda_i(\mathbf{x}, 0)$. The Heaviside function, denoted by $H(\psi(\mathbf{x}))$, is used to indicate the exterior and interior regions, and its derivative is denoted by $\delta(\psi(\mathbf{x}))$. The dynamical system describing the evolution is defined as follows:

$$\begin{aligned} \frac{\partial \psi_i(\mathbf{x}, t)}{\partial t} &= G(\psi_i(\mathbf{x}, t), I) \delta(\psi_i(\mathbf{x}, t)) \\ \psi_i(\mathbf{x}, 0) &= \psi_i^0(\mathbf{x}) \end{aligned} \quad (1)$$

where $G(\psi_i(\mathbf{x}, t), I)$ is a generic term representing an image force and the interactions between ψ_i and ψ_j , where $j \neq i$. We decompose $G(\psi_i(\mathbf{x}, t), I)$ into two *competing* components as

$$\begin{aligned} G(\psi_i(\mathbf{x}, t), I) &= -(g(\psi_i(\mathbf{x}, t), I) \\ &\quad - g^c(\psi_i(\mathbf{x}, t), I)), \end{aligned} \quad (2)$$

where $g(\cdot) \geq 0$ represents an internal image energy of $\psi_i(\mathbf{x}, t)$ and $g^c(\psi_i(\mathbf{x}, t), I) \geq 0$ is the image energy from all other $\psi_j(\mathbf{x}, t)$, $j \neq i$. A negative sign is used in front of equation (2) due to the definition of H for interior region. This

Control-Based Segmentation, Fig. 1 Diagram of the control-based segmentation framework. The feedback compensates for deficiencies in automatic segmentation by utilizing the expert's knowledge

decomposition technique has been used for modeling multiple active contours in different region-based algorithms (Vázquez et al. 2006). On the other hand, since distance information from given points of an image may be implemented using the level set formulation, segmentation algorithms that are based on clustering pixels according to the minimal distance to given seeds naturally fit into this formulation. In particular, the proposed framework is applicable to (1) *region-based active contour models* and (2) *distance-based clustering*.

Region-Based Active Contours

Let $g_r(\psi_i(\mathbf{x}, t), I)$ be a function of statistics for a region ψ_i . The image force $G(\psi_i(\mathbf{x}, t), I)$ can be rewritten as

$$G(\psi_i(\mathbf{x}, t), I) = -(g_r(\psi_i(\mathbf{x}, t), I) - g_r^c(\psi_i(\mathbf{x}, t), I)), \quad (3)$$

where $g_r^c(\psi_i(\mathbf{x}, t), I) = \min_{j \neq i} \{g_r(\psi_j(\mathbf{x}, t), I)\}$. A simple example is the first order statistics defined as

$$g_r(\psi_i(\mathbf{x}, t), I) = \int_{\Lambda} \|I(\mathbf{x}) - \mu_i(t)\|_2^2 H(\psi_i(\mathbf{x}, t)) d\mathbf{x}, \quad (4)$$

where $\mu_i(t)$ is the mean intensity of region Λ_i at time t (Chan and Vese 2001). Other region-based energies (Lankton and Tannenbaum 2008; Gao et al. 2012; Michailovich et al. 2007) may be employed similarly.

Distance-Based Clustering

Distance-based clustering methods assign labels to pixels based on the minimal distance to given seed points. Letting Λ_{x_i} denote the seed region for the i th label, the distance between any point $\mathbf{x}$ and the label is defined as

$$\mathbf{d}(\mathbf{x}, \Lambda_{x_i}) := \min_{y \in \Lambda_{x_i}} \min_{C \in \pi(\mathbf{x}, y)} \int_0^1 g_\gamma(C(p)) \|C'(p)\| dp, \quad (5)$$

where $\pi(\mathbf{x}, y)$ is any path connecting points $\mathbf{x}$ and y and p is the parameterization of the path with metric g_γ . This formulation may be interpreted as a front propagation with an image-dependent speed function $1/g_\gamma$ and implemented by using the level set formulation. The front arriving earlier than any of the other fronts becomes the current front. The force on the current front of ψ_i may be written in the same form as in equation (2):

$$G(\psi_i(\mathbf{x}, t), I) = -(g_d(\psi_i(\mathbf{x}, t), I) - g_d^c(\psi_i(\mathbf{x}, t), I)), \quad (6)$$

with

$$g_d(\psi_i(\mathbf{x}, t), I) = g_\gamma(I)H(\psi_i^{-1}(\mathbf{x}, t) - \min_{j=1, \dots, N} \{\psi_j^{-1}(\mathbf{x}, t)\}) \quad (7)$$

and $g_d^c = g_\gamma(I)$, where $\psi_i^{-1}(\mathbf{x}, t)$ denotes the distance value at point $\mathbf{x}$ and H is the Heaviside function. An example of the function g_γ is based on image gradient information and defined as $g_\gamma(I) = 1 + \|\nabla I\|_2^2$.

Feedback Control and Interactive Segmentation

Suppose the user has an ideal segmentation $\{\psi_i^*(\mathbf{x})\}, i = 1, \dots, N$ in mind. Given this, our goal is to design a feedback control system

$$\begin{aligned} \frac{\partial \psi_i(\mathbf{x}, t)}{\partial t} &= (G(\psi_i(\mathbf{x}, t), I) \\ &\quad + F(\psi_i(\mathbf{x}, t), \psi_i^*(\mathbf{x})))\delta(\psi_i(\mathbf{x}, t)), \\ \psi_i(\mathbf{x}, 0) &= \psi_i^0(\mathbf{x}) \end{aligned}$$

(8) for given constants $v > 0, \mu > 0$.

such that $\lim_{t \rightarrow \infty} \psi_i(\mathbf{x}, t) \rightarrow \psi_i^*(\mathbf{x})$ for $i = 1, \dots, N$, where $F(\psi_i(\mathbf{x}, t), \psi_i^*(\mathbf{x}))$ is the control signal to be determined.

Regulatory Control

Define point-wise error for each region $\xi_i(\mathbf{x}, t)$ and total error $V(\xi, t)$ as

$$\begin{aligned} \xi_i(\mathbf{x}, t) &= \varepsilon(\psi_i(\mathbf{x}, t), \psi_i^*(\mathbf{x})) \\ &\triangleq H(\psi_i(\mathbf{x}, t)) - H(\psi_i^*(\mathbf{x})) \end{aligned} \quad (9)$$

$$V(\xi, t) = \frac{1}{2} \sum_{i=1}^N \int_{\Lambda} \xi_i^2(\mathbf{x}, t) d\mathbf{x}, \quad (10)$$

where $\xi_i(\mathbf{x}, t) \in \{-1, 0, 1\}$ measures the point-wise difference between ψ_i and ψ_i^* at time t . If

ψ^* is given and $V(\xi, t) \in C^1$ with respect to t , the determination of $F(\cdot, \cdot)$ is straightforward by applying the Lyapunov's direct method for stabilization. The control signal uses the bounds of the image-dependent term $g(\cdot, \cdot)$ defined in equation (2):

$$g_M(\mathbf{x}) = \max_{i=1, \dots, N} \{g(\psi_i(\mathbf{x}), I), g^c(\psi_i(\mathbf{x}), I)\} \quad (11)$$

For the dynamical system defined in equation (8), we have the following theorem (Zhu et al. 2018):

Theorem 1 *The control law*

$$F(\psi_i(\mathbf{x}, t), \psi_i^*(\mathbf{x})) = -\alpha_i^2(\mathbf{x}, t)\xi_i(\mathbf{x}, t), \quad (12)$$

where $\alpha_i^2(\mathbf{x}, t) \geq g_M(\mathbf{x})$, asymptotically stabilizes the system (8) from $\{\psi_i(\mathbf{x}, t)\}$ to $\{\psi_i^*(\mathbf{x})\}, i = 1, \dots, N$.

Furthermore, the control law exponentially stabilizes the system with a convergence rate of e^{-vt} when ξ is large in the sense of

$$\begin{aligned} \mu \int_{\Lambda} \delta^2(\psi_i(\mathbf{x}, t))\xi_i^2(\mathbf{x}, t) d\mathbf{x} \\ \leq \int_{\Lambda} \xi_i^2(\mathbf{x}, t) d\mathbf{x}, i = 1, \dots, N \end{aligned} \quad (13)$$

for given constants $v > 0, \mu > 0$.

Examples of Feedback Control-Based Segmentation Methods

A large number of evolutionary methods can be augmented to include user interactions using the proposed design principles. Two representative methods are discussed in this section: (1) classic region-based active contour models and (2) distance-based clustering.

Controlled Region-Based Active Contour Models

The image force $G(\psi_i(\mathbf{x}, t), I)$ described in Sect. 1 is used. Our goal is then how to design the user input u_i^k and U_i based on principles from feedback control theory.

A kernel-based method is employed to model the user input for u_i^k as

$$u_i^k(\mathbf{x}, t_i^{k+}) = h_0(\|\mathbf{x} - \Lambda_{x_i^k}\|_g), \quad (14)$$

where $\|\mathbf{x} - \Lambda_{x_i^k}\|_g$ is the geodesic distance from $\mathbf{x}$ to $\Lambda_{x_i^k}$ in terms of an image based metric g and h_0 is a decreasing function with respect to this distance. Here, we employ $g = 1 + \|\nabla I\|_2^2$ and $h_0 = (d_{\max} - d)/(d_{\max} - d_{\min})$, where $d, d_{\max}, d_{\min}$ are the distance and its corresponding extrema, respectively. The value of $d_{\max}$ controls the maximal range the current input affects. The overall effect for label i is defined as

$$\mathbf{u}_i(\mathbf{x}, t) = \sum_k u_i^k(\mathbf{x}_i^k, t), \quad (15)$$

To propagate and smooth the effect of user input, a diffusion process is applied to $\mathbf{u}_i(\mathbf{x}, t)$ as in Karasev et al. (2013), where

$$\begin{cases} \frac{\partial \mathbf{u}_i}{\partial t} = \mathbf{u}_i + \nabla \cdot [H((\mathbf{u}_i/g_M)^2 - 1)\nabla \mathbf{u}_i] \\ \mathbf{u}_i(\mathbf{x}, 0) = 0 \end{cases} \quad (16)$$

The total user input effect is defined as

$$\begin{aligned} U_i(\mathbf{x}, t) &= J(\mathbf{u}_i(\mathbf{x}, t), \mathbf{u}_i^c(\mathbf{x}, t)) \\ &\triangleq \mathbf{u}_i(\mathbf{x}, t) - \sum_{j \neq i} \mathbf{u}_j(\mathbf{x}, t) \end{aligned} \quad (17)$$

The label error is approximated by

$$\hat{\xi}_i(\mathbf{x}, t) = S(U_i(\mathbf{x}, t)) \triangleq -\text{sign}(U_i(\mathbf{x}, t)). \quad (18)$$

Since we are only certain about the error at where the user scribbled, the strength of the control law is defined in a weighted sense as

$$F(\psi_i(\mathbf{x}, t), \psi_i^*(\mathbf{x})) = -g_M |U_i| \hat{\xi}_i(\mathbf{x}, t). \quad (19)$$

The purpose of weighting is that the user effect decreases as a function of distance to the actual input points. When this distance is large, we

have $g_M |U_i| \ll g_M$. Therefore, the control law drives the system to a balanced location between the force from G and F when the distance is large.

Controlled Distance-Based Clustering

Here we use the simple image force $G(\psi_i(\mathbf{x}, t), I)$ as described in Sect. 1. The control scheme described in the previous section may in principle be extended to the distance-based clustering, but it causes inconsistency between metrics used in the system equation and user input. To resolve this inconsistency, the effect of user input is defined to have the same metric as the system equations

$$\begin{aligned} u_i^k(\mathbf{x}, t) &= \min_{\mathbf{y} \in \Lambda_{x_i^k}} \min_{C \in \theta(\mathbf{x}, \mathbf{y})} \int_0^1 g_\gamma(C(l)) \|C'(l)\| dl \\ u_i^k(\Lambda_{x_i^k}, t_i^k) &= q, \quad u_i^k(\Lambda_{x_i^k}^c, t_i^k) = p \end{aligned} \quad (20)$$

with $q = 0$ and $p = \infty$, where $\theta(\mathbf{x}, \mathbf{y})$ is any path connecting points $\mathbf{x}$ and $\mathbf{y}$ and l is the parameterization of the path with metric g_γ .

The total user input effect is computed as

$$\begin{aligned} U_i(\mathbf{x}, t) &= J(\mathbf{u}_i(\mathbf{x}, t), \mathbf{u}_i^c(\mathbf{x}, t)) \\ &\triangleq \min_{u_k \in \mathbf{u}_i(\mathbf{x}, t)} u_k(\mathbf{x}, t) - \min_{u_k \in \mathbf{u}_i^c(\mathbf{x}, t)} u_k(\mathbf{x}, t). \end{aligned} \quad (21)$$

The effect of user input is propagated as $u_i^k(\mathbf{x}, t)$ evolving. The error estimate is defined as

$$\hat{\xi}_i(\mathbf{x}, t) = S(U_i(\mathbf{x}, t)) \triangleq \text{sign}(U_i(\mathbf{x}, t)). \quad (22)$$

The control law at continuous interval is defined as

$$F(\psi_i(\mathbf{x}, t), \psi_i^*(\mathbf{x})) = -g_M \hat{\xi}_i(\mathbf{x}, t). \quad (23)$$

For each $\mathbf{x}$ at the front $\delta(\psi_i(\mathbf{x}), t)$ with $\hat{\xi}_i(\mathbf{x}, t) = 0$, its distance value $\psi_i^{-1}(\mathbf{x}, t)$ is updated by the $\min\{\mathbf{u}_i(\mathbf{x}, t)\}$ if its distance is smaller. Thus, all distance values are up-to-date when there is no estimated segmentation error.

We give an example of the region-based active contour control segmentation algorithm in Fig. 2.

Conclusion

In this work, we summarized the work of Karasev et al. (2013) and Zhu et al. (2018) for interactive (steerable) closed-loop control formulations for performing the central task of segmentation. This framework allows for a number of design choices; in particular, prior information can be incorporated in the estimators, and the automatic algorithms are replaceable, the control functions can be designed, and the user interactions can change. We should note that open source software is available for the implementation of the algorithms in 3D Slicer www.kitware.com that may be used in just about any platform.

Controllability and Observability

H. L. Trentelman

Johann Bernoulli Institute for Mathematics and Computer Science, University of Groningen, Groningen, AV, The Netherlands

Abstract

State controllability and observability are key properties in linear input–output systems in state-space form. In the state-space approach, the relation between inputs and outputs is represented using the state variables of the system. A natural question is then to what extent it is possible to manipulate the values of the state vector by means of an appropriate choice of the input function. The concepts of controllability, reachability, and null controllability address this issue. Another important question is whether it is possible to uniquely determine the values of the state vector from knowledge of the input and output signals over a given time interval. This question is dealt with using the concept of observability.

Keywords

Controllability · Duality · Indistinguishability · Input–output systems in state-space form · Observability · Reachability

Introduction

In the state-space approach to input–output systems, the relation between input signals and output signals is represented by means of two equations. In the continuous-time case, the first of these equations is a first-order vector differential equation driven by the input signal and is often called *the state equation*. The second equation is an algebraic equation, often called the *output equation*. The unknown in the differential equation is called the *state vector* of the system. Given a particular input signal and initial value of the state vector, the state equation generates

a unique solution, called the state trajectory of the system. The output equation determines the corresponding output signal as a function of this state trajectory and the input signal. Thus, in the state space approach, the input–output behavior of the system is obtained using the state vector as an intermediate variable.

In the context of input–output systems in state-space form, the properties of controllability and observability characterize the interaction between the input, the state, and the output. In particular, controllability describes the ability to manipulate the state vector of the system by applying appropriate input signals. Observability describes the ability to determine the values of the state vector from knowledge of the input and output over a certain time interval. The properties of controllability and observability are fundamental properties that play a major role in the analysis and control of linear input–output systems in state-space form.

Systems with Inputs and Outputs

Consider a continuous-time, linear, time-invariant, input–output system in state-space form represented by the equations

$$\begin{aligned}\dot{x}(t) &= Ax(t) + Bu(t), \\ y(t) &= Cx(t) + Du(t).\end{aligned}\tag{1}$$

This system is referred to as Σ . In Eq. (1), A , B , C , and D are maps (or matrices), and the functions x , u , and y are considered to be defined on the real axis $\mathbb{R}$ or on any subinterval of it. In particular, one often assumes the domain of definition to be the nonnegative part of $\mathbb{R}$, which is without loss of generality since the system is time-invariant. The function u is called the *input*, and its values are assumed to be given. The class of admissible input functions is denoted by $\mathbf{U}$. Often, $\mathbf{U}$ is the class of piecewise continuous or locally integrable functions, but for most purposes, the exact class from which the input functions are chosen is not important. We assume that input functions take values in an m -dimensional space $\mathcal{U}$, which we often identify with $\mathbb{R}^m$. The first equation of Σ is an ordinary differential

equation for the variable x . For a given initial value of x and input function u , the function x is completely determined by this equation. The variable x is called the *state variable* and it is assumed to take values in an n -dimensional space $\mathcal{X}$. The space $\mathcal{X}$ is called the *state space*. It is usually identified with $\mathbb{R}^n$. Finally, y is called the *output* of the system and takes values in a p -dimensional space $\mathcal{Y}$, which we identify with $\mathbb{R}^p$. Since the system Σ is completely determined by the maps (or matrices) A , B , C , and D , we identify Σ with the quadruple (A, B, C, D) .

The solution of the differential equation of Σ with initial value $x(0) = x_0$ is denoted as $x_u(t, x_0)$. It can be given explicitly using the variation-of-constants formula, namely,

$$x_u(t, x_0) = e^{At}x_0 + \int_0^t e^{A(t-\tau)}Bu(\tau) d\tau. \quad (2)$$

The corresponding value of y is denoted by $y_u(t, x_0)$. As a consequence of (2), we have

$$y_u(t, x_0) = Ce^{At}x_0 + \int_0^t K(t-\tau)u(\tau) d\tau + Du(t), \quad (3)$$

where $K(t) := Ce^{At}B$. In the case $D = 0$, it is customary to call $K(t)$ the *impulse response*. In the general case, one would call the distribution $K(t) + D\delta(t)$ the impulse response.

Controllability

Controllability is concerned with the ability to manipulate the state by choosing an appropriate input signal, thus steering the current state to a desired future state in a given finite time. Thus, in particular, in the differential equation in (1), we study the relation between u and x . We investigate to what extent one can influence the state x by a suitable choice of the input u .

For this purpose, we introduce the (at time T) *reachable space* $\mathcal{W}_T$, defined as the space of points x_1 for which there exists an input u such that $x_u(T, 0) = x_1$, i.e., the set of points that can be reached from the origin at time T . It follows

from the linearity of the differential equation that $\mathcal{W}_T$ is a linear subspace of $\mathcal{X}$. In fact, (2) implies

$$\mathcal{W}_T = \left\{ \int_0^T e^{A(T-\tau)}Bu(\tau) d\tau \mid u \in \mathbf{U} \right\}. \quad (4)$$

We call system Σ *reachable at time T* if every point can be reached from the origin, i.e., if $\mathcal{W}_T = \mathcal{X}$. It follows from (2) that if the system is reachable at time T , every point can be reached from every point at time T , because the condition for the point x_1 to be reachable from x_0 at time T is

$$x_1 - e^{AT}x_0 \in \mathcal{W}_T.$$

The property that every point is reachable from any point in a given time interval $[0, T]$ is called *controllability (at T)*. Finally, we have the concept of *null controllability*, i.e., the possibility to reach the origin from an arbitrary initial point. According to (2), for a point x_0 to be null controllable at T , we must have

$$e^{AT}x_0 + \int_0^T e^{A(T-\tau)}Bu(\tau) d\tau = 0$$

for some $u \in \mathbf{U}$. We observe that x_0 is null controllable at T (by the control u) if and only if $-e^{AT}x_0$ is reachable at T (by the control u). Since e^{AT} is invertible, we see that Σ is null controllable at T if and only if Σ is reachable at T . Henceforth, we refer to the equivalent properties reachability, controllability, null controllability simply as controllability (at T). It should be remarked that the equivalence of these concepts does not hold in other situations, e.g., for discrete-time systems. We intend to obtain an explicit expression for the space $\mathcal{W}_T$ and, based on this, an explicit condition for controllability. This is provided by the following result.

Theorem 1 *Let η be an n -dimensional row vector and $T > 0$. Then the following statements are equivalent:*

1. $\eta \perp \mathcal{W}_T$ (i.e., $\eta x = 0$ for all $x \in \mathcal{W}_T$).
2. $\eta e^{tA}B = 0$ for $0 \leq t \leq T$.
3. $\eta A^k B = 0$ for $k = 0, 1, 2, \dots$
4. $\eta (B \ AB \ \dots \ A^{n-1}B) = 0$.

Proof.

- (i) $\Leftrightarrow$ (ii) If $\eta \perp \mathcal{W}_T$, then by Eq. (4):

$$\int_0^T \eta e^{A(T-\tau)} B u(\tau) d\tau = 0 \quad (5)$$

for every $u \in \mathbf{U}$. Choosing $u(t) = B^T e^{A^T(T-t)} \eta^T$ for $0 \leq t \leq T$ yields

$$\int_0^T \left\| \eta e^{A(T-\tau)} B \right\|^2 d\tau = 0,$$

from which (ii) follows. Conversely, assume that (ii) holds. Then (5) holds and hence (i) follows.

- (ii) $\Leftrightarrow$ (iii) This is obtained by power series expansion of $e^{At} \left(= \sum_{k=0}^{\infty} \frac{t^k}{k!} A^k \right)$.
 (iii) $\Leftrightarrow$ (iv) This follows immediately from the evaluation of the vector-matrix product.
 (iv) $\Leftrightarrow$ (iii) This implication is based on the Cayley-Hamilton Theorem. According to this theorem, A^n is a linear combination of $I, A, \dots, A^{n-1}$. By induction, it follows that A^k ($k > n$) is a linear combination of $I, A, \dots, A^{n-1}$ as well. Therefore, $\eta A^k B = 0$ for $k = 0, 1, \dots, n-1$ implies that $\eta A^k B = 0$ for all $k \in \mathbb{N}$. $\square$

As an immediate consequence of the previous theorem, we find that at time T reachable subspace $\mathcal{W}_T$ can be expressed in terms of the maps A and B as follows. $\square$

Corollary 1

$$\mathcal{W}_T = \text{im} (B \quad AB \quad \dots \quad A^{n-1}B).$$

This implies that, in fact, $\mathcal{W}_T$ is independent of T , for $T > 0$. Because of this, we often use $\mathcal{W}$ instead of $\mathcal{W}_T$ and call this subspace the reachable subspace of Σ . This subspace of the state space has the following geometric characterization in terms of the maps A and B .

Corollary 2 $\mathcal{W}$ is the smallest A -invariant subspace containing $B := \text{im} B$. Explicitly, $\mathcal{W}$ is A -invariant, $B \subset \mathcal{W}$, and any A -invariant sub-

space $\mathcal{L}$ satisfying $B \subset \mathcal{L}$ also satisfies $\mathcal{W} \subset \mathcal{L}$. We denote the smallest A -invariant subspace containing B by $\langle A|B \rangle$, so that we can write $\mathcal{W} = \langle A|B \rangle$. For the space $\langle A|B \rangle$, we have the following explicit formula

$$\langle A|B \rangle = B + AB + \dots + A^{n-1}B.$$

Corollary 3 The following statements are equivalent.

1. There exists $T > 0$ such that system Σ is controllable at T .
2. $\langle A|B \rangle = \mathcal{X}$.
3. $\text{Rank} (B \quad AB \quad \dots \quad A^{n-1}B) = n$.
4. The system Σ is controllable at T for all $T > 0$.

We say that the matrix pair (A, B) is *controllable* if one of these equivalent conditions is satisfied.

Example 1 Let A and B be defined by

$$A := \begin{pmatrix} -2 & -6 \\ 2 & 5 \end{pmatrix}, \quad B := \begin{pmatrix} -3 \\ 2 \end{pmatrix}.$$

Then $(B \quad AB) = \begin{pmatrix} -3 & -6 \\ 2 & 4 \end{pmatrix}$, $\text{rank}(B \quad AB) = 1$, and consequently, (A, B) is not controllable. The reachable subspace is the span of $(B \quad AB)$, i.e., the line given by the equation $2x_1 + 3x_2 = 0$. This can also be seen as follows. Let $z := 2x_1 + 3x_2$, then $\dot{z} = z$. Hence, if $z(0) = 0$, which is the case if $x(0) = 0$, we must have $z(t) = 0$ for all $t \geq 0$.

Observability

In this section, we include the second of equations (1), $y = Cx + Du$, in our considerations. Specifically, we investigate to what extent it is possible to reconstruct the state x if the input u and the output y are known. The motivation is that we often can measure the output and prescribe (and hence know) the input, whereas the state variable is *hidden*.

Definition 1 Two states x_0 and x_1 in $\mathcal{X}$ are called *indistinguishable* on the interval $[0, T]$ if for any

input u we have $y_u(t, x_0) = y_u(t, x_1)$, for all $0 \leq t \leq T$.

Hence, x_0 and x_1 are indistinguishable if they give rise to the same output values for every input u . According to (3), for x_0 and x_1 to be indistinguishable on $[0, T]$, we must have that

$$\begin{aligned} Ce^{At}x_0 + \int_0^t K(t-\tau)u(\tau)d\tau + Du(t) \\ = Ce^{At}x_1 + \int_0^t K(t-\tau)u(\tau)d\tau + Du(t) \end{aligned}$$

for $0 \leq t \leq T$ and for any input signal u . We note that the input signal does not affect distinguishability, i.e., if one u is able to distinguish between two states, then any input is. In fact, x_0 and x_1 are indistinguishable if and only if $Ce^{At}x_0 = Ce^{At}x_1$ ($0 \leq t \leq T$). Obviously, x_0 and x_1 are indistinguishable if and only if $v := x_0 - x_1$ and 0 are indistinguishable. By applying Theorem 1 with $\eta = v^T$ nonzero and transposing the equations, it follows that $Ce^{At}x_0 = Ce^{At}x_1$ ($0 \leq t \leq T$) if and only if $Ce^{At}v = 0$ ($0 \leq t \leq T$) and hence if and only if $CA^k v = 0$ ($k = 0, 1, 2, \dots$). The Cayley-Hamilton Theorem implies that we need to consider the first n terms only, i.e.,

$$\begin{pmatrix} C \\ CA \\ CA^2 \\ \vdots \\ CA^{n-1} \end{pmatrix} v = 0. \quad (6)$$

As a consequence, the distinguishability of two vectors does not depend on T . The space of vectors v for which (6) holds is denoted $\langle \ker C|A \rangle$ and called the *unobservable subspace*. It is equivalently characterized as the intersection of the spaces $\ker CA^k$ for $k = 0, \dots, n-1$, i.e.,

$$\langle \ker C|A \rangle = \bigcap_{k=0}^{n-1} \ker CA^k.$$

Equivalently, $\langle \ker C|A \rangle$ is the largest A -invariant subspace contained in $\ker C$. Finally, another characterization is “ $v \in \langle \ker C|A \rangle$ if and only if

$y_0(t, v)$ is identically zero,” where the subscript “0” refers to the zero input.

Definition 2 System Σ is called *observable* if any two distinct states are not indistinguishable. The previous considerations immediately lead to the result.

Theorem 2 The following statements are equivalent.

1. The system Σ is observable.
2. Every nonzero state is not indistinguishable from the origin.
3. $\langle \ker C|A \rangle = 0$.
4. $Ce^{At}v = 0$ ($0 \leq t \leq T$) $\Rightarrow v = 0$.

$$5. \text{Rank} \begin{pmatrix} C \\ CA \\ CA^2 \\ \vdots \\ CA^{n-1} \end{pmatrix} = n.$$

Since observability is completely determined by the matrix pair (C, A) , we will say “ (C, A) is observable” instead of “system Σ is observable.”

There is a remarkable relation between the controllability and observability properties, which is referred to as *duality*. This property is most conspicuous from the conditions (3) in Corollary 3 and (5) in Theorem 2, respectively. Specifically, (C, A) is observable if and only if (A^T, C^T) is controllable. As a consequence of duality, many theorems on controllability can be translated into theorems on observability and vice versa by mere transposition of matrices.

Example 2 Let

$$A := \begin{pmatrix} -11 & 3 \\ -3 & -5 \end{pmatrix}, \quad B := \begin{pmatrix} 1 \\ 1 \end{pmatrix},$$

$$C := (1 \quad -1),$$

Then

$$\text{rank} \begin{pmatrix} C \\ CA \end{pmatrix} = \text{rank} \begin{pmatrix} 1 & -1 \\ -8 & 8 \end{pmatrix} = 1,$$

hence, (C, A) is not observable. Notice that if $v \in \langle \ker C|A \rangle$ and $u = 0$, identically, then $y = 0$, identically. In this example, $\langle \ker C|A \rangle$ is the span of $(1, 1)^T$.

Summary and Future Directions

The property of controllability can be tested by means of a rank test on a matrix involving the maps A and B appearing in the state equation of the system. Alternatively, controllability is equivalent to the property that the reachable subspace of the system is equal to the state space. The property of observability allows a rank test on a matrix involving the maps A and C appearing in the system equations. An alternative characterization of this property is that the unobservable subspace of the system is equal to the zero subspace. Concepts of controllability and observability have also been defined for discrete-time systems and, more generally, for time-varying systems and for continuous-time and discrete-time nonlinear systems.

Controllability of Network Systems

Fabio Pasqualetti
Department of Mechanical Engineering,
University of California at Riverside, Riverside,
CA, USA

Abstract

Several natural and man-made systems are often represented as complex networks, since

their dynamic behavior depends to a large extent upon the properties of their interconnection structure. Electrical power grids, mass transportation systems, and cellular networks are instances of modern technological networks, while metabolic and brain networks are biological examples. The ability to control and reconfigure complex networks via external controls is fundamental to guarantee reliable and efficient network functionalities. In this note, we review recent advances and methods that characterize fundamental controllability properties and limitations of network systems.

Keywords

Network · Controllability · Structural analysis · Optimization

Introduction

Network systems are dynamical systems that arise from the interconnection of simpler dynamical units. Such systems are typically described by a graph representing the interconnections among the different units, a state containing the characteristic values of all units, and a map describing the dynamics of the state. In a simple and commonly used setting, the interconnections among the units are captured by a directed graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$, where $\mathcal{V} = \{1, \dots, n\}$ and $\mathcal{E} \subseteq \mathcal{V} \times \mathcal{V}$ are the vertex and edge sets, respectively, the state of each node is a real number, the network state is $x \in \mathbb{R}^n$, and the state dynamics are captured by the linear, discrete time, noiseless, and time-invariant recursion

$$x(t+1) = Ax(t). \quad (1)$$

In (1), the matrix $A = [a_{ij}]$ is a weighted adjacency matrix of $\mathcal{G}$, where $a_{ij} = 0$ if $(i, j) \notin \mathcal{E}$ and a_{ij} equals an arbitrary real number if $(i, j) \in \mathcal{E}$. Further, it is often assumed that a subset of control nodes $\mathcal{K} = \{k_1, \dots, k_m\} \subseteq \mathcal{V}$ can be independently manipulated, which leads to the controlled network dynamics

$$x(t+1) = Ax(t) + B_{\mathcal{K}}u_{\mathcal{K}}(t), \quad (2)$$

where $B_{\mathcal{K}} = [e_{k_1} \cdots e_{k_m}]$, e_i is the i -th canonical vector of dimension n , and $u_{\mathcal{K}} : \mathbb{N}_{\geq 0} \rightarrow \mathbb{R}^m$ is the control signal injected in the network via the nodes $\mathcal{K}$.

The network (2) is controllable in T steps by the control nodes $\mathcal{K}$ if there exists an input $u_{\mathcal{K}}$ such that $x(0) = x_0$ and $x(T) = x_d$, for any initial state x_0 and final state x_d . Several equivalent conditions ensuring controllability (Kalman et al. (1963) and Kailath (1980)) are known. For instance, the network (2) is controllable in T steps by the control nodes $\mathcal{K}$ if and only if the T -steps controllability matrix

$$C_{\mathcal{K},T} = [B_{\mathcal{K}} \ AB_{\mathcal{K}} \ A^2B_{\mathcal{K}} \ \cdots \ A^{T-1}B_{\mathcal{K}}]$$

is full rank or, equivalently, if and only if the T -steps controllability Gramian

$$W_{\mathcal{K},T} = \sum_{\tau=0}^{T-1} A^{\tau} B_{\mathcal{K}} B_{\mathcal{K}}^{\top} (A^{\top})^{\tau} = C_{\mathcal{K},T} C_{\mathcal{K},T}^{\top}$$

is invertible. When the final time satisfies $T \geq n$, network controllability is also equivalent to the matrix $[\lambda I - A \ B_{\mathcal{K}}]$ being full rank for every eigenvalue λ of A . Finally, when A is (Schur) stable and the final time satisfies $T = \infty$, network controllability is ensured by the existence of a unique positive-definite solution X to the Lyapunov equation $AXA^{\top} - X + B_{\mathcal{K}}B_{\mathcal{K}}^{\top} = 0$ (in fact, $X = W_{\mathcal{K},\infty}$). It should be noticed that the above tests for network controllability are descriptive, in the sense that they allow to test controllability of a network by a set of control nodes, but not prescriptive because they do not indicate how to select control nodes, or how to modify the network structure and weights, to ensure controllability of network systems.

Results on the Controllability of Network Systems

In this section, we review important approaches and results for the network controllability prob-

lem. We divide the results into three main categories, which differ in the required knowledge of the network matrices, in the type of information that they can provide, and in their numerical complexity.

Structural Controllability of Network Systems

A convenient method to select a set of control nodes to guarantee controllability of the network system (2) originates from the theory of structural systems. To formalize this discussion, let $a_{\mathcal{E}} = \{a_{ij} : (i, j) \in \mathcal{E}\}_{\text{ordered}}$ denote the set of nonzero entries of A in lexicographic order, and notice that the determinant $\det(W_{\mathcal{K}, T}) = \phi(a_{\mathcal{E}})$ is a polynomial function with variables $a_{\mathcal{E}}$. Then, the network (2) is uncontrollable when the weights $a_{\mathcal{E}}$ are chosen so that $\phi(a_{\mathcal{E}}) = 0$. Let $\mathcal{S}$ contain the choices of weights that render the network (2) uncontrollable; that is,

$$\mathcal{S} = \{z \in \mathbb{R}^d : \phi(z_1, \dots, z_d) = 0\}, \quad (3)$$

where $d = |\mathcal{E}| = |a_{\mathcal{E}}|$. Notice that $\mathcal{S}$ describes an algebraic variety of $\mathbb{R}^d$ (Wonham 1985). This implies that controllability of (2) is a *generic property*, because it fails to hold on an algebraic variety of the parameter space (Markus et al. 1962; Wonham 1985; Tchoń 1983). Consequently, when assessing controllability of the network (2) as a function of the weights, only two mutually exclusive cases are possible:

1. either there is *no* choice of weights a_{ij} , with $a_{ij} = 0$ if $(i, j) \notin \mathcal{E}$, rendering the network (2) controllable; or
2. the network (2) is controllable for all choices of weights a_{ij} , with $a_{ij} = 0$ if $(i, j) \notin \mathcal{E}$, except those belonging to the proper algebraic variety $\mathcal{S} \subset \mathbb{R}^d$. (The variety $\mathcal{S}$ of $\mathbb{R}^d$ is proper when $\mathcal{S} \neq \mathbb{R}^d$ (Wonham 1985).)

Loosely speaking, if one can find a choice of weights such that the network (2) is controllable, then *almost all* choices of weights yield a controllable network. In this case, the network is said to be *structurally controllable* (Davison and Wang 1973; Lin 1974; Reinschke 1988).

Following the above reasoning, necessary and sufficient graph-theoretic conditions on the network graph $\mathcal{G}$ and the set of control nodes $\mathcal{K}$ have been identified to guarantee controllability of network systems, as well as algorithms for the selection of control sets with minimum cardinality. For instance, Reinschke (1988) finds network controllability conditions using the notions of *cycle family* and *rooted path*, while the seminal work of Lin (1974) employs the notion of spanning *cacti* and Murota (2012) uses bipartite-graph criteria. Algorithms, and their complexity, to determine minimal sets of control nodes for structural controllability are presented, among others, in Olshevsky (2014) and Pequito et al. (2015). The case of strong structural controllability, where controllability must be satisfied for any nonzero choice of the network weights, is studied, for instance, in Mayeda and Yamada (1979), Menara et al. (2017), Jarczyk et al. (2011), and Jia et al. (2019), while the case of constrained entries is discussed in Menara et al. (2019), Mousavi et al. (2017), and Li et al. (2018). We conclude noting that structural controllability methods require the knowledge of only the network graph $\mathcal{G}$ and can only provide generic results that are independent of the network weights. Thus, even if a network system is structurally controllable, the actual numerical realization (i.e., the choice of network weights) may not be controllable.

Model-Based Controllability of Network Systems

The notion of structural controllability is qualitative, in the sense that it is independent of the network weights and unable to capture any property of the input signal that steers the network system to the desired state. As a matter of fact, most connected network systems are controllable even with a single control node (Reinschke 1988; Menara et al. 2019; Gu et al. 2015), although the properties of their control inputs may vary significantly as a function of the network size, weights, and number of control nodes. To quantify a degree of controllability, one convenient measure is the *energy* of the control input to

transfer the network state from $x_0 = 0$ to a desired state x_d . Specifically, define the energy of the control input $u_{\mathcal{K}}$ as

$$E(u_{\mathcal{K}}, T) = \sum_{\tau=0}^{T-1} \|u_{\mathcal{K}}(\tau)\|_2^2,$$

where T is the control horizon, and recall (Kailath 1980) that the unique control input that steers the network from $x(0) = 0$ to $x(T) = x_d$ with minimum energy is

$$u_{\mathcal{K}}^*(t) = B_{\mathcal{K}}^T (A^T)^{T-t-1} W_{\mathcal{K},T}^{-1} x_d. \quad (4)$$

Moreover, the energy of (4) satisfies $E(u_{\mathcal{K}}^*, T) = x_d^T W_{\mathcal{K},T}^{-1} x_d$. Different measures of the controllability degree of network systems can be obtained using the notion of control energy. For instance, the worst-case input energy is (In what follows, $\lambda_{\min}(M)$, $\text{Trace}(M)$, and $\text{Det}(M)$ denote the smallest eigenvalue, the trace, and the determinant of the square matrix M , respectively.)

$$E_{\max} = \max_{\|x_d\|=1} x_d^T W_{\mathcal{K},T}^{-1} x_d = \lambda_{\min}^{-1}(W_{\mathcal{K},T}), \quad (5)$$

while the average input energy (over all target states with unit norm) can be computed to be $E_{\text{average}} = \text{Trace}(W_{\mathcal{K},T}^{-1})$. The metrics $E_{\text{volume}} = \text{Det}(W_{\mathcal{K},T})$, which is proportional to the volume of the ellipsoid containing the states that can be reached with a unit-energy control input, and $E_{\text{impulse}} = \text{Trace}(W_{\mathcal{K},T})$, which measures the energy of the network response to a unit impulsive input, have also been adopted to measure the controllability degree of a network system (Müller and Weber 1972; Marx et al. 2004; Shaker and Tahavori 2012). The selection of control nodes for the optimization of these metrics is usually a computationally hard combinatorial problem (Olshevsky 2017, 2013), for which heuristics, typically without performance guarantees, and non-scalable optimization procedures have been proposed (Summers and Lygeros 2014;

Van De Wal and De Jager 2001; Sharon and Rex 1999).

Recent studies have demonstrated connections between the control energy of a network and its structure and parameters. For instance, it has been shown that most complex networks cannot be controlled by few nodes, because the control energy grows exponentially with the network cardinality (Pasqualetti et al. 2014). This property ensures that existing complex structures are in fact robust to targeted perturbations or failures. On the other hand, there exist topologies that violate this paradigm, where few controllers can arbitrarily reprogram large structures with little effort (Pasqualetti and Zampieri 2014; Zhao and Pasqualetti 2019, 2018). Control energy also grows significantly when the eigenvalues of the network matrix are clustered in a region of the complex plane (Olshevsky et al. 2016), when the diameter of the network grows linearly with its size (Bianchin et al. 2015), and also for a large class of networks with continuous-time dynamics (Zhao and Pasqualetti 2017). Finally, Bof et al. (2017) highlight an interesting connection between the controllability degree of a network and popular centrality measures.

Data-Driven Controllability of Network Systems

While the techniques described above require accurate knowledge of the network structure and, possibly, its weights, a recent line of research aims to assess and evaluate network controllability in a model-free and data-driven fashion. To this aim, the availability of a set of N control experiments is assumed, where the i -th control experiment consists of applying a randomly chosen input sequence $u_{\mathcal{K},i}$ to (2), and measuring the system state at time T , namely, $x_i = A^T x_0 + C_{\mathcal{K},T} u_{\mathcal{K},i}$. Thus, in vector form, the available data is assumed to be

$$X = [x_1 \cdots x_N] \quad \text{and} \quad U = [u_{\mathcal{K},1} \cdots u_{\mathcal{K},N}]. \quad (6)$$

In this setting, if the input matrix U is of full row rank (Baggio et al. 2019), then the minimum-

energy input (4) can equivalently be computed (in vector form) as

$$u_K^* = (I - UK(UK)^\dagger)UX^\dagger x_d = (XU^\dagger)^\dagger x_f \quad (7)$$

where $K = \text{Ker}(X)$ denotes the null space of the matrix X . Data-driven expressions of the controllability Gramian can be derived directly from (7), or following the approach described in Baggio et al. (2019). The data-driven approach to study network controllability problems, which has already been extended to different control settings (Baggio and Pasqualetti 2020; Coulson et al. 2019; Tabuada et al. 2017; Persis and Tesi 2020; Berberich and Allgöwer 2019; van Waarde et al. 2019), may provide solutions to the shortcomings of model-based techniques to study controllability of large networks (Sun and Motter 2013; Antoulas et al. 2002).

Summary and Future Directions

Network controllability is an active field of research with broad implications for natural, social, and technological systems (Gu et al. 2015; Acemoglu et al. 2010; Rajapakse et al. 2011; Skardal and Arenas 2015; Rahmani et al. 2009). Different methods and measures have been proposed and are currently being developed. Potentially interesting research directions include the study of controllability for networks with time-varying topologies, as well as a more flexible and dynamic choice of the control nodes, which could in principle overcome the energy limitations of a fixed selection of control nodes in large systems. The problem of defining controllability metrics and algorithms for closed-loop network systems is also fundamentally important, as it would allow us to design and operate network systems robustly against noise and modeling uncertainties. The design of efficient model-based and data-driven node selection algorithms is an important outstanding aspect, as the numerical limitations and assumptions of existing methods prevent their applicability to large systems. Finally, the development

of a controllability theory for networks with nonlinear dynamics is also critically lacking, and it remains necessary to ensure the applicability of this field of research to real-world network systems. To conclude, we stress that this note reflects specific advances and is not meant to be comprehensive.

Controller Performance Monitoring

Sirish L. Shah

Department of Chemical and Materials Engineering, University of Alberta Edmonton, Edmonton, AB, Canada

Abstract

Process control performance is a cornerstone of operational excellence in a broad spectrum of industries such as refining, petrochemicals, pulp and paper, mineral processing, power systems, and wastewater treatment. Control performance assessment and monitoring applications have become mainstream in these industries and are changing the maintenance methodology surrounding control assets from predictive to condition based. The large numbers of these assets on most sites compared to the number of maintenance and control personnel have made monitoring and diagnosing control problems challenging. For this reason, automated controller performance monitoring technologies have been readily embraced by these industries.

This entry discusses the theory as well as practical application of controller performance monitoring tools as a requisite for monitoring and maintaining basic as well as advanced process control (APC) assets in the process industry. The section begins with the introduction to the theory of performance assessment as a technique for assessing the performance of the basic control loops in a plant. Performance assessment allows detection of performance degradation in the basic control loops in a plant by monitoring the variance in the process variable and comparing it to that of a minimum variance controller. Other metrics of controller performance are also reviewed. The resulting indices of performance give an indication of the level of performance of the controller and an indication

of the action required to improve its performance; the diagnosis of poor performance may lead one to look at remediation alternatives such as retuning controller parameters or process reengineering to reduce delays or implementation of feed-forward control or attribute poor performance to faulty actuators or other process nonlinearities.

Keywords

Time series analysis · Minimum variance control · Control loop performance assessment · Performance monitoring · Fault detection and diagnosis

Introduction

A typical industrial process, as in a petroleum refinery or a petrochemical complex, includes thousands of control loops. Instrumentation technicians and engineers maintain and service these loops but rather infrequently. However, industrial studies have shown that as many as 60% of control loops may have poor tuning or configuration or actuator problems and may therefore be responsible for suboptimal process performance. As a result, monitoring of such control strategies to detect and diagnose cause(s) of unsatisfactory performance has received increasing attention from industrial engineers. Specifically the methodology of data-based controller performance monitoring (CPM) is able to answer questions such as the following: Is the controller doing its job satisfactorily, and, if not, what is the cause of poor performance?

The performance of process control assets is monitored on a daily basis and compared with industry benchmarks. The monitoring system also provides diagnostic guidance for poorly performing control assets. Many industrial sites have established reporting and remediation workflows to ensure that improvement activities are carried out in an expedient manner. Plant-wide performance metrics can provide insight into

company-wide process control performance. Closed-loop tuning and modeling tools can also be deployed to aid with the improvement activities. Survey articles by Thornhill and Horch (2007) and Shardt et al. (2012) provide a good overview of the overall state of CPM and the related diagnosis issues. CPM software is now readily available from most DCS vendors and has already been implemented successfully at many large-scale industrial sites throughout the world.

Univariate Control Loop Performance Assessment with Minimum Variance Control as Benchmark

It has been shown by Harris (1989) that for a system with time delay d , a portion of the output variance is feedback control invariant and can be estimated from routine operating data. This is the so-called minimum variance output. Consider the closed-loop system shown in Fig. 1, where Q is the controller transfer function, $\tilde{T}$ is the process transfer function, d is the process delay (in terms of sample periods), and N is the disturbance transfer function driven by random white-noise sequence, a_t .

In the regulatory mode (when the set point is constant), the closed-loop transfer function relating the process output and the disturbance is given by

$$\text{Closed-loop response: } y_t = \left(\frac{N}{1 + q^{-d} \tilde{T} Q} \right) a_t$$

Controller Performance Monitoring, Fig. 1 Block diagram of a regulatory control loop

Note that all transfer functions are expressed for the discrete time case in terms of the backshift operator, q^{-1} . N represents the disturbance transfer function with numerator and denominator polynomials in q^{-1} . The division of the numerator by the denominator can be rewritten as: $N = F + q^{-d} R$, where the quotient term $F = F_0 + F_1 q^{-1} + \dots + F_{d-1} q^{-(d-1)}$ is a polynomial of order $(d-1)$ and the remainder R is a transfer function. The closed-loop transfer function can be reexpressed, after algebraic manipulation as

$$\begin{aligned} y_t &= \left(\frac{N}{1 + q^{-d} \tilde{T} Q} \right) a_t \\ &= \left(\frac{F + q^{-d} R}{1 + q^{-d} \tilde{T} Q} \right) a_t \\ &= \left(\frac{F(1 + q^{-d} \tilde{T} Q) + q^{-d} (R - F \tilde{T} Q)}{1 + q^{-d} \tilde{T} Q} \right) a_t \\ &= \left(F + q^{-d} \frac{R - F \tilde{T} Q}{1 + q^{-d} \tilde{T} Q} \right) a_t \\ &= \underbrace{F_0 a_t + F_1 a_{t-1} + \dots + F_{d-1} a_{t-d+1}}_{e_t} \\ &\quad + \underbrace{L_0 a_{t-d} + L_1 a_{t-d-1} + \dots}_{w_{t-d}} \end{aligned}$$

The closed-loop output can then be expressed as

$$y_t = e_t + w_{t-d}$$

where $e_t = F a_t$ corresponds to the first $d-1$ lags of the closed-loop expression for the output, y_t , and more importantly is independent of the controller, Q , or it is controller invariant, while w_{t-d} is dependent on the controller. The variance of the output is then given by

$$\text{Var}(y_t) = \text{Var}(e_t) + \text{Var}(w_{t-d}) \geq \text{Var}(e_t)$$

Since e_t is controller invariant, it provides the lower bound on the output variance. This is naturally achieved if $w_{t-d} = 0$, that is, when $R = F \tilde{T} Q$ or when the controller is a minimum

variance controller with $Q = \frac{R}{F\bar{T}}$. If the total output variance is denoted as $Var(y_t) = \sigma^2$, then the lowest achievable variance is $Var(e_t) = \sigma_{mv}^2$. To obtain an estimate of the lowest achievable variance from the time series of the process output, one needs to model the closed-loop output data y_t by a moving average process such as

$$y_t = \underbrace{f_0 a_t + f_1 a_{t-1} + \cdots + f_{d-1} a_{t-(d-1)}}_{e_t} + f_d a_{t-d} + f_{d+1} a_{t-(d+1)} + \cdots \quad (1)$$

The controller-invariant term e_t can then be estimated by time series analysis of routine closed-loop operating data and subsequently used as a benchmark measure of theoretically achievable absolute lower bound of output variance to assess control loop performance. Harris (1989), Desbor-

ough and Harris (1992), and Huang and Shah (1999) have derived algorithms for the calculation of this minimum variance term.

Multiplying Eq. (1) by $a_t, a_{t-1}, \dots, a_{t-d+1}$, respectively, and then taking the expectation of both sides of the equation yield the sample covariance terms:

$$\left. \begin{aligned} r_{ya}(0) &= E[y_t a_t] = f_0 \sigma_a^2 \\ r_{ya}(1) &= E[y_t a_{t-1}] = f_1 \sigma_a^2 \\ r_{ya}(2) &= E[y_t a_{t-2}] = f_2 \sigma_a^2 \\ &\vdots \\ r_{ya}(d-1) &= E[y_t a_{t-d+1}] = f_{d-1} \sigma_a^2 \end{aligned} \right\} \quad (2)$$

The minimum variance or the invariant portion of output variance is

$$\left. \begin{aligned} \sigma_{mv}^2 &= (f_0^2 + f_1^2 + f_2^2 + \cdots + f_{d-1}^2) \sigma_a^2 \\ &= \left[\left(\frac{r_{ya}(0)}{\sigma_a^2} \right)^2 + \left(\frac{r_{ya}(1)}{\sigma_a^2} \right)^2 + \left(\frac{r_{ya}(2)}{\sigma_a^2} \right)^2 + \left(\frac{r_{ya}(d-1)}{\sigma_a^2} \right)^2 \right] \sigma_a^2 \\ &= [r_{ya}^2(0) + r_{ya}^2(1) + r_{ya}^2(2) + \cdots + r_{ya}^2(d-1)] / \sigma_a^2 \end{aligned} \right\} \quad (3)$$

A measure of controller performance index can then be defined as

$$\eta(d) = \sigma_{mv}^2 / \sigma_y^2 \quad (4)$$

Substituting Eq. (3) into Eq. (4) yields

$$\begin{aligned} \eta(d) &= [r_{ya}^2(0) + r_{ya}^2(1) + r_{ya}^2(2) + \cdots + r_{ya}^2(d-1)] / \sigma_y^2 \sigma_a^2 \\ &= \rho_{ya}^2(0) + \rho_{ya}^2(1) + \rho_{ya}^2(2) + \cdots + \rho_{ya}^2(d-1) \\ &= ZZ^T \end{aligned}$$

where Z is the vector of cross correlation coefficients between y_t and a_t for lags 0 to $d-1$ and is denoted as

$$Z = [\rho_{ya}(0) \rho_{ya}(1) \rho_{ya}(2) \cdots \rho_{ya}(d-1)]$$

Although a_t is unknown, it can be replaced by the estimated innovation sequence $\hat{a}_t$. The estimate

$\hat{a}_t$ is obtained by whitening the process output variable y_t via time series analysis. This algorithm is denoted as the FCOR algorithm for Filtering and CORrelation analysis (Huang and Shah 1999). This derivation assumes that the delay, d , be known a priori. In practice, however, a priori knowledge of time delays may not always be available. It is therefore useful to

assume a range of time delays and then calculate performance indices over this range of the time delays. The indices over a range of time delays are also known as extended horizon performance indices (Thornhill et al. 1999). Through pattern recognition, one can tell the performance of the loop by visualizing the patterns of the performance indices versus time delays. There is a clear relation between performance indices curve and the impulse response curve of the control loop.

Consider a simple case where the process is subject to random disturbances. Figure 2 is one example of performance evaluation for a control loop in the presence of disturbances. This figure shows time series of process variable data for both loops in the top 2 plots, closed-loop impulse responses (left columns), and corresponding performance indices (labeled as PI on the right columns). From the impulse responses, one can see that the loop under the first set of tuning constants (denoted as TAG1.PV) has better performance; the loop under the second set of tuning constants (denoted as TAG5.PV) has oscillatory behavior, indicating a relatively poor control performance. With performance index “1” indicating the best possible performance and index “0” indicating the worst performance, performance indices for the first controller tuning (shown on the upper-right plot) approach “1” within four time lags, while performance indices for the second controller tuning (shown on the bottom-right plot) take ten time lags to approach “0.7.” In addition, performance indices for the second tuning show ripples as they approach an asymptotic limit, indicating a possible oscillation in the loop.

Notice that one cannot rank performance of these two controller settings from the noisy time series data. Instead, we can calculate performance indices over a range of time delays (from 1 to 10). The result is shown on the right column plots of Fig. 2. These simulations correspond to the same process with different controller tuning constants. It is clear from these plots that performance indices trajectory depends on dynamics of the disturbance and controller tuning.

It is important to note that the minimum variance is just one of several benchmarks for

obtaining a controller performance metric. It is seldom practical to implement minimum variance control as it typically will require aggressive actuator action. However, the minimum variance benchmark serves to provide an indication of the opportunity in improving control performance; that is, should the performance index $\eta(d)$ be near or just above zero, then it gives the user an idea of the benefits possible in improving the control performance of that loop.

Performance Assessment and Diagnosis of Univariate Control Loop Using Alternative Performance Indicators

In addition to the performance index for performance assessment, there are several alternative indicators of control loop performance. These are discussed next.

Autocorrelation function The autocorrelation function (ACF) of the output error, shown in Fig. 3, is an approximate measure of how close the existing controller is to minimum variance condition or how predictable the error is over the time horizon of interest. If the controller is under minimum variance condition, then the autocorrelation function should decay to zero after “ $d - 1$ ” lags where “ d ” is the delay of the process. In other words, there should be no predictable information beyond time lag $d - 1$. The rate at which the autocorrelation decays to zero after “ $d - 1$ ” lags indicates how close the existing controller is to the minimum variance condition. Since it is straightforward to calculate autocorrelation using process data, the autocorrelation function is often used as a first-pass test before carrying out further performance analysis.

Impulse response An impulse response function curve represents the closed-loop impulse response between the whitened disturbance sequence and the process output. This function is a direct measure of how well the controller is performing in rejecting disturbances or tracking set-point changes. Under stochastic framework,

Controller Performance Monitoring, Fig. 2 Time series of process variable (top), corresponding impulse responses (left column) and their performance indices (right column)

Controller Performance Monitoring,

Fig. 3 Autocorrelation function of the controller error

Controller Performance Monitoring,

Fig. 4 Impulse responses estimated from routine operating data

this impulse response function may be calculated using time series model such as an autoregressive moving average (ARMA) or autoregressive integrated moving average (ARIMA) model. Once an ARMA type of time series model is estimated, the infinite-order moving average representation of the model shown in Eq. (1) can be obtained through a long division of the ARMA model. As shown in Huang and Shah (1999), the coefficients of the moving average model, Eq. (1), are the closed-loop impulse response coefficients of the process between whitened disturbances and the process output. Figure 4 shows closed-loop impulse responses of a control loop with two different control tunings. Clearly they denote two different closed-loop dynamic responses: one is slow and smooth, and the other one is relatively fast and slightly oscillatory. The sum of square of the impulse response coefficients is the variance of the data.

Spectral analysis The closed-loop frequency response of the process is an alternative way to assess control loop performance. Spectral analysis of output data easily allows one to

detect oscillations, offsets, and measurement noise present in the process. The closed-loop frequency response is often plotted together with the closed-loop frequency response under minimum variance control. This is to check the possibility of performance improvement through controller tunings. The comparison gives a measure of how close the existing controller is to the minimum variance condition. In addition, it also provides the frequency range in which the controller significantly deviates from minimum variance condition. Large deviation in the low-frequency range typically indicates lack of integral action or weak proportional gain. Large peaks in the medium-frequency range typically indicate an overtuned controller or presence of oscillatory disturbances. Large deviation in the high-frequency range typically indicates significant measurement noise. As an illustrative example, frequency responses of two control loops are shown in Fig. 5. The top graph of the figure shows that closed-loop frequency response of the existing controller is almost the same as the frequency response under minimum variance control. A peak at the mid-frequency indicates

Controller Performance Monitoring, Fig. 5 Frequency response estimated from routine operating data

possible overtuned control. The bottom graph of Fig. 5 shows that the frequency response of the existing controller is oscillatory, indicating a possible overtuned controller or the presence of an oscillatory disturbance at the peak frequency; otherwise the controller is close to minimum variance condition.

Segmentation of performance indices Most process data exhibit time-varying dynamics; i.e., the process transfer function or the disturbance transfer function is time variant. Performance assessment with a nonoverlapping sliding data window that can track time-varying dynamics is therefore often desirable. For example, segmentation of data may lead to some insight into any cyclical behavior of the process variation

in controller performance during, e.g., due to day versus night process operation or due to shift changes. Figure 6 is an example of performance segmentation over a 200 data wide window.

Performance Assessment of Univariate Control Loops Using User-Specified Benchmarks

The increasing level of global competitiveness has pushed chemical plants into high-performance operating regions that require advanced process control technology. See the articles ► [Control Hierarchy of Large Processing Plants: An Overview](#) and ► [Control Structure Selection](#). Consequently, industry has

Controller Performance Monitoring,

Fig. 6 Performance indices for segmented data (each of window length 200 points)

an increasing need to upgrade the conventional PID controllers to advanced control systems. The most natural questions to ask for such an upgrading are as follows. Has the advanced controller improved performance as expected? If yes, where is the improvement and can it be justified? Has the advanced controller been tuned to its full capacity? Can this improvement also be achieved by simply retuning the existing traditional (e.g., PID) controllers? (see ► [PID Control](#)). In other words, what is the cost versus benefit of implementing an advanced controller? Unlike performance assessment using minimum variance control as benchmark, the solution to this problem does not require a priori knowledge of time delays. Two possible relative benchmarks may be chosen: one is the historical data benchmark or reference data set benchmark, and the other is a user-specified benchmark.

The purpose of reference data set benchmarking is to compare performance of the existing controller with the previous controller during the “normal” operation of the process. This reference data set may represent the process when the controller performance is considered satisfactory with respect to meeting the performance objectives. The reference data set should be representative of the normal conditions that the process is expected to operate at; i.e., the disturbances and set-point changes entering into the process should not be unusually different. This analysis provides the user with a relative performance index (RPI) which compares the existing control loop

performance with a reference control loop benchmark chosen by the user. The RPI is bounded by $0 \leq RPI \leq \infty$, with “<1” indicating deteriorated performance, “1” indicating no change of performance, and “>1” indicating improved performance. Figure 7 shows a result of reference data set benchmarking. The impulse response of the benchmark or reference data smoothly decays to zero, indicating good performance of the controller. After one increases the proportional gain of the controller, the impulse response shows oscillatory behavior, with an $RPI = 0.4$, indicating deteriorated performance due to the oscillation.

In some cases one may wish to specify certain desired closed-loop dynamics and carry out performance analysis with respect to such desired dynamics. One such desired dynamic benchmark is the closed-loop settling time. As an illustrative example, Figure 8 shows a system where a settling time of ten sampling units is desired for a process with a delay of five sampling units. The impulse responses show that the existing loop is close to the desired performance and the value of $RPI = 0.9918$ confirms this. Thus no further tuning of the loop is necessary.

Diagnosis of Poorly Performing Loops

Whereas detection of poorly performing loops is now relatively simple, the task of diagnosing

Controller Performance Monitoring,

Fig. 7 Reference benchmarking based on impulse responses

Controller Performance Monitoring,

Fig. 8 User-specified benchmark based on impulse responses

reason(s) for poor performance and how to “mend” the loop is generally not straightforward. The reasons for poor performance could be any one of interactions between various control loops, overtuned or undertuned controller settings, process nonlinearity, poor controller configuration (meaning poor choice of pairing a process (or controlled) variable with a manipulative variable loop), or actuator problems such as stiction, large delays, and severe disturbances. Several studies have focused on the diagnosis issues related to actuator problems (Håagglund 2002; Choudhury et al. 2008; Srinivasan and Rengaswamy 2008; Xiang and Lakshminarayanan 2009; de Souza et al. 2012). Shardt et al. (2012) has given an overview of the overall state of CPM and the related diagnosis issues.

Industrial Applications of CPM Technology

As remarked earlier, CPM software is now readily available from most DCS vendors and has already been implemented successfully at several large-scale industrial sites. A summary of just two of many large-scale industrial implementations of CPM technology appears below. It gives a clear evidence of the impact of this control technology and how readily it has been embraced by industry (Shah et al. 2014).

BASF Controller Performance Monitoring Application

As part of its excellence initiative OPAL 21 (Optimization of Production Antwerp and

Ludwigshafen), BASF has implemented the CPM strategy on more than 30,000 control loops at its Ludwigshafen site in Germany and on over 10,000 loops at its Antwerp production facility in Belgium. The key factor in using this technology effectively is to combine process knowledge, basic chemical engineering, and control expertise to develop solutions for the indicated control problems that are diagnosed in the CPM software (Wolff et al. 2012).

Saudi Aramco Controller Performance Monitoring Practice

As part of its process control improvement initiative, Saudi Aramco has deployed CPM on approximately 15,000 PID loops, 50 MPC applications, and 500 smart positioners across multiple operating facilities.

The operational philosophy of the CPM engine is incorporated in the continuous improvement process at BASF and Aramco, whereby all loops are monitored in real time and a holistic performance picture is obtained for the entire plant. Unit-wide performance metrics are displayed in effective color-coded graphic forms to effectively convey the analytics information of the process.

Concluding Remarks

In summary, industrial control systems are designed and implemented or upgraded with a particular objective in mind. The controller performance monitoring methodology discussed here will permit automated and repeated reviews of the design, tuning, and upgrading of the control loops. Poor design, tuning, or upgrading of the control loops can be detected, and repeated performance monitoring will indicate which loops should be retuned or which loops have not been effectively upgraded when changes in the disturbances, in the process, or in the controller itself occur. Obviously better design, tuning, and upgrading will mean that the process will operate at a point close to the economic optimum, leading to energy savings, improved safety, efficient utilization of raw materials, higher product

yields, and more consistent product qualities. This entry has summarized the major features available in recent commercial software packages for control loop performance assessment. The illustrative examples have demonstrated the applicability of this new technique when applied to process data.

This entry has also illustrated how controllers, whether in hardware or software form, should be treated like “capital assets” and how there should be routine monitoring to ensure that they perform close to the economic optimum and that the benefits of good regulatory control will be achieved.

Department of Electrical Engineering,
University of California, Los Angeles, CA, USA

Abstract

The analysis and design of Cyber-Physical Systems (CPS) remain a challenge in no small part due to the intricate interactions between cyber and physical components. In this entry we address the problem of synthesizing a cyber component so that its interaction with a CPS satisfies a desired specification by construction. This paradigm is often termed “formal controller synthesis”, or simply “synthesis”, and is an alternative to the more commonly used verification paradigm.

Keywords

Controller synthesis · Formal synthesis · Synthesis · CPS

What is Formal Controller Synthesis?

The analysis and design of Cyber-Physical Systems (CPS) remain a challenge in no small part due to the intricate interactions between cyber and physical components. In this entry we address the problem of synthesizing a cyber component so that its interaction with a CPS satisfies a desired specification by construction. This paradigm is often termed “formal controller synthesis,” or simply “synthesis,” and is an alternative to the more commonly used verification paradigm.

Each paradigm has its advantages and disadvantages. In the verification paradigm, one first constructs the cyber component and then verifies that its interaction with the CPS satisfies the desired specifications. When the verification step identifies that the specification is not satisfied, it is necessary to re-design the cyber component and to re-verify it. This results in a cycle, alternating between the design and verification phases that can be time consuming. In contrast, in the synthesis paradigm, a cyber component is produced along with a proof that it meets the desired specifications. Hence, iteration is not required, and for this reason, synthesis is an example of a *correct-by-construction* or *correct-by-design* methodology. Synthesis, however, is a much more difficult algorithmic problem than verification. In fact, one can view verification as a particular case of synthesis: if the result of synthesis for a CPS is that no cyber component is required, it constitutes a proof that the CPS already meets the specification. For this reason, verification is applicable to a much wider class of CPS than synthesis.

In this entry we review the existing approaches in the literature for CPS synthesis. Rather than attempting to be exhaustive, we focus on the key ideas that underlie this design methodology. In

particular, an important line of research that is not discussed is that of stochastic systems.

Problem Formulation

To formalize the synthesis problem, we need to introduce formal models for systems, specifications, and system composition.

Modeling Systems

We consider a fairly abstract notion of system that can be used to describe both cyber and physical components.

Definition 1 (System) A system Σ is a tuple $\Sigma = (X, X_0, U, F, Y, H)$ consisting of:

- a set of states X ;
- a set of initial states $X_0 \subseteq X$;
- a set of inputs U ;
- a set-valued map $F : X \times U \rightarrow 2^X$ where 2^X denotes the set of all subsets of X ;
- a set of outputs Y ;
- an output map $H : X \rightarrow Y$;

The dynamics is described by the map F , and its set-valued nature is used to model non-determinism that can arise from coarse modeling or from the effect of exogenous disturbances. Given a state $x \in X$ and input $u \in U$, the next state is known to belong to the set $F(x, u)$ and is only uniquely determined when $F(x, u)$ is a singleton. The dynamics of a system gives rise to its *behavior*.

Definition 2 (System behavior) An internal behavior ξ of a system Σ is an infinite sequence $\xi \in X^{\mathbb{N}}$ such that:

1. $\xi(0) \in X_0$;
2. There exists an infinite sequence of inputs $v \in U^{\mathbb{N}}$ such that $\xi(i+1) \in F(\xi(i), v(i))$ for all $i \in \mathbb{N}$.

Every internal behavior induces an external behavior $\zeta \in Y^{\mathbb{N}}$ defined by $\zeta(i) = H(\xi(i))$ for all $i \in \mathbb{N}$. We denote the set of external behaviors of a system Σ by $\mathcal{B}(\Sigma)$.

When modeling cyber components, the set of states X is typically finite, and thus we call such systems *finite systems*. However, models for physical components typically require (uncountably) infinite sets of states.

Modeling Specifications

Specification for the desired behavior of a system Σ are typically given as a set of desired behaviors $S \subseteq Y^{\mathbb{N}}$. In practice, the set S is given either as the output behavior of a finite system Σ_S , i.e., $S = \mathcal{B}(\Sigma_S)$, or as a temporal logic formula. It is outside the scope of this entry to venture into temporal logic. The interested reader can find all the relevant details in the literature, e.g., Emerson (1990) and Stirling (1992). For the purpose of understanding the CPS synthesis problem, it suffices to know that a temporal logic formula φ defines S as the set of all infinite sequences $\zeta \in Y^{\mathbb{N}}$ satisfying φ .

To make these ideas more concrete, let us assume we separate the set of states X into safe and unsafe states. We can then define Y to be the set **{safe, unsafe}** and define H by mapping safe states $x \in X$ to $H(x) = \mathbf{safe}$ and unsafe states $x \in X$ to $H(x) = \mathbf{unsafe}$. Consider now the formula $\varphi = \Diamond \mathbf{safe}$ requiring the output along an external behavior to eventually become **safe**. In other words, φ requires the state along an internal behavior to eventually become safe and thus produce the output **safe**. An external behavior $\zeta \in Y^{\mathbb{N}}$ satisfies φ , denoted by $\zeta \models \varphi$, if there exists an $i \in \mathbb{N}$ for which we have $\zeta(i) = \mathbf{safe}$. We could consider instead the formula $\varphi = \Box \mathbf{safe}$ requiring all the states visited along an internal behavior to be safe states. An external behavior $\zeta \in Y^{\mathbb{N}}$ satisfies $\Box \mathbf{safe}$ if for every $i \in \mathbb{N}$ we have $\zeta(i) = \mathbf{safe}$. The specification S defined by the formula $\Box \mathbf{safe}$ would then contain a single external behavior:

safe safe safe ...,

whereas for $\varphi = \Diamond \mathbf{safe}$, the set S would consist of all the external behaviors of the form:

$\underbrace{Y Y Y Y}_{k \text{ times}} \mathbf{safe} Y Y Y \dots$,

with $k \in \mathbb{N}$ and where Y represents an output that can either be **safe** or **unsafe**.

Composing Systems

The notion of composition describes the system that results from the concurrent execution of two systems mediated by their interaction. The specific way in which they interact is described by an interconnection relation.

Definition 3 Let $S_a = (X_a, X_{a0}, U_a, F_a, Y_a, H_a)$ and $S_b = (X_b, X_{b0}, U_b, F_b, Y_b, H_b)$ be two systems and let $\mathcal{I} \subseteq X_a \times X_b \times U_a \times U_b$ be a relation. The composition of S_a with S_b with interconnection relation $\mathcal{I}$, denoted by $S_a \times_{\mathcal{I}} S_b$, is the system $(X_{ab}, X_{ab0}, U_{ab}, F_{ab}, Y_{ab}, H_{ab})$ consisting of:

- $X_{ab} = \{(x_a, x_b) \in X_a \times X_b \mid \exists(u_a, u_b) \in U_a \times U_b (x_a, x_b, u_a, u_b) \in \mathcal{I}\};$
- $X_{ab0} = X_{ab} \cap (X_{a0} \times X_{b0});$
- $U_{ab} = U_a \times U_b;$
- $(x'_a, x'_b) \in F_{ab}(x_a, x_b, u_a, u_b)$ if the following three conditions hold:
 1. $x'_a \in F_a(x_a, u_a);$
 2. $x'_b \in F_b(x_b, u_b);$
 3. $(x_a, x_b, u_a, u_b) \in \mathcal{I};$
- $Y_{ab} = Y_a \times Y_b;$
- $H_{ab}(x_a, x_b) = (H_a(x_a), H_b(x_b)).$

To illustrate the notion of composition, consider an arbitrary system S_a that is to be controlled by a feedback control law $K : X_a \rightarrow U_a$. We can define a new system S_b by $(X_a, X_{a0}, U_a, F_a, U_a, K)$ where we used the output map to describe the control law. By connecting the output of S_b to the input of S_a , we will be forcing the inputs of S_a to be chosen according to the control law. This can be accomplished by defining the interconnection relation $\mathcal{I}$ as the set of tuples $(x_a, x_b, u_a, u_b) \in X_a \times X_b \times U_a \times U_b$ satisfying $x_a = x_b$ and $u_a = K(x_b) = H_b(x_b)$. By suitably defining $\mathcal{I}$, we can model series, parallel, and other types of interconnections between systems as detailed in Tabuada (2009).

The Formal Controller Synthesis Problem

We now mathematically define the synthesis problem discussed in this entry.

Problem 1 (Formal controller synthesis)

Given a system Σ and a specification S , synthesize a system C (the controller) and an interconnection relation $\mathcal{I}$ so that:

$$\mathcal{B}(C \times_{\mathcal{I}} \Sigma) \subseteq S.$$

When the specification S is given by a temporal logic formula, we write $C \times_{\mathcal{I}} \Sigma \models \varphi$ to denote that every $\zeta \in \mathcal{B}(C \times_{\mathcal{I}} \Sigma)$ satisfies φ .

This version of the synthesis problem is sometimes termed *behavioral inclusion* since it requires the external behavior of $C \times_{\mathcal{I}} \Sigma$ to be included in S . However, there are properties that cannot be specified via behavioral inclusion and other variations of the synthesis problem exist in the literature, e.g., Tabuada (2008, 2009) and Belta et al. (2017).

Abstraction-Based Synthesis

The synthesis problem is much better understood for cyber systems. Mathematically, this means that Σ is a finite system, and we are seeking a finite controller C . For this reason, CPS synthesis is often reduced to a synthesis problem for finite systems. Such reduction can be accomplished by constructing a *finite abstraction* $\tilde{\Sigma}$ of the system Σ modeling a CPS, so that a controller $\tilde{C}$ enforcing the specification S on $\tilde{\Sigma}$ can be refined to a controller C enforcing the specification S on Σ . In symbols, we have:

$$\mathcal{B}(\tilde{C} \times_{\tilde{\mathcal{I}}} \tilde{\Sigma}) \subseteq S \implies \mathcal{B}(C \times_{\mathcal{I}} \Sigma) \subseteq S. \quad (1)$$

This solution strategy implicitly assumes that:

1. One can synthesize $\tilde{C}$ when $\tilde{\Sigma}$ is finite.
2. One can construct the abstraction $\tilde{\Sigma}$ from Σ .
3. One can construct C from $\tilde{C}$.
4. It is easier to perform the preceding three steps than directly synthesizing C .

We now address each of these assumptions in detail.

Formal Controller Synthesis for Finite Systems

Synthesis for finite systems has a long history, and this problem is fairly well understood. Although the search for more efficient synthesis algorithms is still an active area of research, several software tools are available for this purpose. The interested readers can find an introduction to synthesis for finite systems in, e.g., Chapter 27 of Clarke et al. (2018), Chapter 5 of Belta et al. (2017), and a gentler introduction, for the special case of safety and reachability specifications, in Chapter 6 of Tabuada (2009). A different approach to synthesis for finite systems, based on discrete-event systems, can be found in, e.g., Kumar and Garg (1995) and Cassandras and Lafortune (2008).

Construction of Finite Abstractions

Finite abstractions of differential equation models for physical components can be categorized in two classes: *exact* and *approximate*. Both classes are based on the idea of aggregating several states of Σ into a single state in $\tilde{\Sigma}$ in such a way that any synthesized controller $\tilde{C}$ for $\tilde{\Sigma}$ can be refined to a controller C for Σ , i.e., implication (1) holds.

Historically, the idea of using finite abstractions for control was proposed in several papers, e.g., Caines and Wei (1998), Koutsoukos et al. (2000), Fřrstner et al. (2002), and Moor and Raisch (2002), but the first systematic construction of abstractions only appeared several years later. The first class of systems known to admit exact finite abstractions was discrete-time controllable linear systems Tabuada and Pappas (2006), and this enabled, for the first time, the synthesis of controllers enforcing temporal logic specifications on discrete-time linear systems. The key technical idea was to observe that the Brunovsky normal form of controllable linear systems behaves as a finite-state shift register on equivalence classes of states for a suitably defined equivalence relation. A different technique for piecewise linear control systems in continuous time was

first introduced in Habets and Schuppen (2004) to study control problems and then extended in Belta and Habets (2006) to a class on nonlinear systems called multi-affine. This construction exploited the observation that one can determine if all the solutions of a linear differential equation originating inside a simplex will remain within or leave the simplex, by analyzing the linear differential equation at the simplex's vertices. It was then proposed in Kloetzer and Belta (2008) to use this analysis technique as a constructive way to build finite abstractions of multi-affine control systems.

Since these earlier papers, several other extensions and improvements have been proposed in the literature. However, it was also recognized that the class of control systems admitting exact finite abstractions was limited. A major step forward occurred when the notion of *approximate bisimulation* was proposed for control systems in Girard and Pappas (2007) since it enabled the construction of *approximate* finite abstractions for smooth nonlinear systems Pola et al. (2008) and even switched nonlinear systems Girard et al. (2010). The property upon which these first constructions of finite abstractions were based is incremental input-to-state stability and requires, intuitively, that trajectories starting from close initial conditions remain close provided they are produced by inputs that also remain close. Based on this property, it is possible to approximately represent a tube of trajectories in Σ by a single trajectory inside this tube that is then used to build $\tilde{\Sigma}$. These ideas were later extended by showing that weaker forms of abstractions are still possible even in the absence of incremental input-to-state stability Zamani et al. (2012), Liu (2017). Further developments are described in Sect. 1.

Refinement of Controllers

The process of constructing C from $\tilde{C}$ is called controller refinement. Under suitable technical assumptions, the notions of approximate simulation and approximate alternating simulation relation Pola and Tabuada (2009), Tabuada (2009) guarantee that any controller $\tilde{C}$ satisfying $\mathcal{B}(\tilde{C} \times \bar{j}$

$\tilde{\Sigma}) \subseteq S$ can be refined to a controller C satisfying $B(C \times_I \Sigma) \subseteq S$. In general, C can be quite large as it contains $\tilde{C} \times_{\tilde{J}} \tilde{\Sigma}$. Simplifying the controller refinement process and reducing the resulting controller size were some of the motivations for the notion of *feedback refinement relation* introduced in Reissig et al. (2017). This notion results in a stronger requirement than the one imposed by approximate simulation relations but has the advantage of leading to controllers that only require a quantized version of the state. Similar ideas had already been investigated in Girard (2013) in the more specific context of safety and reachability specifications.

Abstraction-Based Synthesis vs Direct Synthesis

The advantage of abstraction-based synthesis is that once $\tilde{\Sigma}$ is available, it can be used to synthesize controllers for different specifications. In other words, $\tilde{\Sigma}$ is specification-agnostic. However, this is also a disadvantage since the construction of abstractions is the main computational bottleneck in abstraction-based synthesis and much of the abstraction may be irrelevant for enforcing a desired specification. This observation led several researchers to investigate specification-guided synthesis techniques. These techniques combine the construction of abstractions with the synthesis of the controller and have the advantage of only computing the part of the abstraction that is relevant for enforcing the given specification. This leads to considerable speedups in the synthesis process. Several different techniques are available in the literature and include the use of on-the-fly abstraction/synthesis techniques (Pola et al. 2012; Rungger and Stursberg 2012), multi-scale abstractions (Girard et al. 2016), and lazy abstraction/synthesis (Hsu et al. 2018; Hussien and Tabuada 2018).

Compositional Synthesis

A different approach to speedup synthesis is based on compositionality. Most CPS result from the composition of smaller modules. Hence, it is natural to exploit this structure for the construc-

tion of abstractions as well as for the synthesis of controllers. Consider a system $\Sigma = \Sigma_1 \times_I \Sigma_2$. In order to construct an abstraction $\tilde{\Sigma}$ of Σ , we can first abstract Σ_1 into $\tilde{\Sigma}_1$, abstract Σ_2 into $\tilde{\Sigma}_2$, and then compose these abstractions into $\tilde{\Sigma}_1 \times_{\tilde{J}} \tilde{\Sigma}_2$. Different technical assumptions and abstractions techniques would then guarantee that $\tilde{\Sigma}_1 \times_{\tilde{J}} \tilde{\Sigma}_2$ is an abstraction of Σ . Since the time complexity of computing $\tilde{\Sigma}_1 \times_{\tilde{J}} \tilde{\Sigma}_2$ is typically smaller than the time complexity of directly computing an abstraction $\tilde{\Sigma}$, the compositional approach is superior in this regard. However, existing compositional techniques result in abstractions that are more conservative than if directly computing an abstraction of Σ . This trade-off has to be carefully considered in the context of the specific system being controlled and the different techniques being used. Since the first investigations (Tazaki and Imura 2008; Reißig 2010) into compositionality in the context of finite abstractions, several techniques were developed including the use of feedback linearizability (Hussien et al. 2017), dissipative systems theory (Zamani and Arcak 2018), overlapping subsystems (Meyer et al. 2018), weak interaction between components (Mallik et al. 2019), and small gain principles (Pola et al. 2016; Swikir and Zamani 2019), among others.

Synthesis for Special Classes of Properties

Another research direction that has proved very useful is the use of specific structural properties of a system to simplify the construction of abstractions or the synthesis of controllers. Examples of such properties include large numbers of similar subsystems and mode counting specifications (Nilsson and Ozay 2016), monotonicity (Kim et al. 2017), and mixed monotonicity (Coogan and Arcak 2017). When specifications only restrict how many subsystems are in each mode of operation, termed mode counting specifications, the abstractions required for synthesis are simpler, thereby substantially reducing the complexity of synthesis. The authors of Nilsson and Ozay (2016) provide synthesis examples with thousands of subsystems. Monotonicity and mixed monotonicity are properties

of differential equations that can be leveraged for the same purpose of simplifying the construction of abstractions and reducing the complexity of synthesis.

Tools

The wide diversity of techniques used for synthesis is also reflected in the diversity of existing tools. Some are now of only historic significance, while others are still being actively maintained. An incomplete list includes PES-SOA (Mazo et al. 2010), LTLMoP (Finucane et al. 2010), TuLiP (Wongpiromsarn et al. 2011), CoSyMa (Mouelhi et al. 2013), SCOTS (Rungger and Zamani 2016), DSSynth (Abate et al. 2017), Sapo (Dreossi 2017), ROCS (Li and Liu 2018), and conPAS2 (Belta 2010).

Abstract

This entry presents a summarizing overview of the key problems in controlling complex network systems consisting of ensembles of interacting linear or nonlinear dynamical systems. After presenting a brief introduction and motivation to the problem, the main approaches to control the collective behavior of such ensembles are discussed together with the current open problems and challenges.

Keywords

Nonlinear control · Complex systems · Network control systems · Multi-agent systems · Control of complex networks

Introduction and Motivation

The traditional feedback paradigm where the output of a single system, e.g., the speed of a car or the level of water in a reservoir, needs to be adjusted as a function of its mismatch against some desired reference value has been increasingly challenged by modern applications. Examples include congestion control in communication networks, control of road traffic, energy balance and distribution in smart grids, and gene regulation in synthetic biological networks to name just a few (Newman et al. 2006; Strogatz 2001).

What makes all of these applications different from a traditional “plant” in control is their distributed, multi-agent nature and their ability to exhibit properties at the macroscopic level that cannot be predicted or analyzed by solely studying agents’ behavior at the microscopic level (Boccaletti et al. 2006; Chen et al. 2014). We name systems exhibiting emerging properties as “complex” to indicate that unfolding their behavior requires a multiscale approach bridging the gap between the scale at which agents operate (the microscopic level) with that where emerging properties arise (the macroscopic level).

A classical example of emerging property often observed in nature and technology is synchronization where an ensemble of interconnected (nonlinear) agents converges toward the same asymptotic solution (Pikovsky et al. 2001; Dörfler and Bullo 2014; Boccaletti et al. 2018). (This is related to the consensus problem in control where typically such a solution is some equilibrium point (Olfati-Saber et al. 2007); also see articles on ► “Consensus of Complex Multi-agent Systems” and ► “Averaging Algorithms and Consensus”). Synchronization is just an example of coordinated collective behavior. Other instances of relevance in applications are pattern formation, flocking behavior, platooning, cluster or group synchronization, etc.

In recent years, the need has become more and more pressing of devising feedback strategies to control the emergence of desired macroscopic properties and steer the collective behavior of

complex systems. This is due to epochal changes in traditional applications such as the transition from power grids to smart grids (Dobson 2013; Doerfler et al. 2013), the interest for new applications such as the control of synthetic biological systems (Del Vecchio et al. 2018), or the need to address pressing open challenges such as climate change, reducing congestion and fuel consumption in traffic applications, and controlling the behavior of flocks of drones or swarms of microrobots.

The challenge for control is to deal with large ensembles of dynamical systems, whose individual dynamics is often nonlinear, interacting with each other over a web of complex interconnections (Liu and Barabási 2016). As noted in the physics literature, such networks of interconnections can have complex structures and are often very far from being regular lattices (Newman 2003). Therefore, the structure of the graph describing the interconnections between the agents in the system plays an important role that cannot be neglected. Also the interconnections themselves between the agents can be time-varying, intermittent, affected by delays, and switched or described by nonlinear interaction functions (e.g., Meng et al. (2018) and Almeida et al. (2017)). Still in applications, collective behavior must be finely controlled, and coordination must be achieved in a distributed manner despite heterogeneities among the agents (think of biological applications!), disturbances, and noise.

Some crucial questions for control are therefore how to achieve, maintain, and steer the collective behavior of a complex network onto a desired solution, how to do so via distributed and decentralized estimation and control strategies, and, last but not least, how to formally prove convergence of the network toward the desired synchronous solution.

There is also a more fundamental challenge underlying all of the previous ones. Typically, the aim is to control the collective behavior of the complex system of interest at the macroscopic level by acting on the individual agents at the microscopic level. So how can we close the loop across these different scales?

The goal of this entry is to present a review of some existing solutions to these problems. Giving an exhaustive review of all the existing results is well beyond the scope of this contribution. Therefore, I have decided to focus on those approaches that rather than being specific to some application domain are more general in their formulation and can be proved formally to converge. Many other strategies have been proposed in the literature both in the control theoretic and physics communities. Exhaustive reviews can be found in many review papers and books in the literature (see, for example, Liu and Barabási 2016; Meyn 2007; Su and Wang 2013).

Modelling Complex Systems

To uncover their dynamics and control complex systems (also referred to as complex networks in the applied science literature), one needs to bring together three fundamental ingredients: (i) a model describing the dynamics of each individual agent in the ensemble, (ii) some communication (or interaction) protocol describing what information is being exchanged among neighboring agents, and (iii) the structure of the interconnections between different agents.

In a general framework, each agent can be thought of as a generic nonlinear control system of the form

$$\dot{x}_i = f_i(x_i) + g_i(x_i)u_i, \quad i = 1, \dots, N \quad (1)$$

where $x_i \in R^n$ is the state vector describing the agent dynamics and $u_i \in R^m$ is the input through which the agent communicates with its neighbors. Note that in consensus problems, the vector field is chosen so as to model networks of simple or higher-order integrators.

The interaction between neighboring agents can be modelled by means of an appropriate coupling law. The choice is application-dependent. A common choice, for example, in the consensus literature, is to assume linear diffusive coupling among the nodes, i.e., to set

$$u_i = \sigma \sum_{j=1}^N a_{ij}(x_j - x_i) \quad (2)$$

where σ is some common constant gain describing the strength of the interaction and a_{ij} is 1 if node i and node j are interconnected or 0 otherwise. Other models are also possible including delays, different gains associated with each link in the network, adaptive coupling laws, etc.

Finally, agents in the network communicate via some network structure encoding the topology of their interconnections. Networks associated with complex systems typically consist of many vertices (or nodes) linked together by relatively fewer edges (or links). The network structure can be represented by its associated graph, say $\mathcal{G}$, that using graph theoretic tools can be encoded by its corresponding adjacency matrix, $\mathcal{A}$, or more commonly via the graph Laplacian, $\mathcal{L}$ (for a review of the properties of these matrices, see Newman (2003) and references therein). To describe the network structures, we can use a set of characteristic features such as the degree k of a given vertex, defined as the number of its connections, the average degree, and the degree distributions. Different types of networks can then be identified such as random graphs, hierarchical networks, small-world networks, or scale-free networks (see Newman (2003) for an exhaustive review).

Often, in the literature on control of complex systems, some simplifying assumptions are made. In particular it is assumed that all agents are identical, i.e., $f_i = f_j = f$, that the interaction protocol is linear and diffusive, and that the structure of the network is static and undirected. Also, it is typically assumed that the input vector field $g_i(x)$ is the identity matrix and $m = n$. We will start by making the same assumptions and then discuss the implications of their relaxations and extensions proposed in the vast literature on controlling complex systems both from the control theoretic and the physics communities.

Under the assumptions mentioned above, the “open-loop” behavior of a multi-agent complex system can be described as

$$\dot{x}_i = f(x_i) + \sigma \sum_{j=1}^N \mathcal{L}_{ij} x_j, \quad i = 1, \dots, N \quad (3)$$

with $\mathcal{L}_{ij}$ being the elements of the network Laplacian describing the interconnection among nodes and where we have assumed linear diffusive coupling functions and nodes sharing identical nonlinear dynamics.

Controlling Collective Behavior

In general given a complex system of interest, because of its nature, control can be exerted via three different strategies or a combination of them. Specifically, control can be achieved by controlling (i) the network nodes or (ii) the edge dynamics (e.g., rendering the coupling function adaptive) or (iii) by varying in real time the network structure (e.g., switching on or off certain edges, rewiring the topology of the interconnections, etc.) (DeLellis et al. 2010). This opens a variety of possibilities to control the collective behavior of a complex system, with the latter approach being the most cumbersome and still little explored in the literature because of its computational complexity and the lack of a formal approach to prove convergence.

Here to illustrate some of the key aspects related to the control problem, we use the representative case of achieving synchronization in a network of the form (3) assuming that such convergence cannot be achieved in the absence of control or that one wishes to steer the synchronous behavior toward a desired solution. A typical example of such a scenario is that of ensembles of chaotic nonlinear systems, often used in the literature as a benchmark problem (Tang et al. 2014).

The crucial idea to achieve this goal is inspired from natural systems such as the heart tissue or swarms of honeybees where a relatively small number of agents in the ensemble take local control decisions that propagate to the entire group via the existing interconnections among nodes in the network. In the heart tissue, for instance, the so-called pacemaker cells are instructed to

increase or decrease the beating frequency. They are a relatively smaller number of all the cells in the tissue, but as information propagates to neighboring cells, the synchronous beating of the heart at the desired frequency is attained. Similarly, in a swarm of honeybees relocating from one location to another, a small number of *explorer bees* scout for the new location and, once decided, communicate its position to other individuals in the swarm causing information to propagate in the social network and the whole swarm to reach the desired site (Chen et al. 2014). *Pinning control* is the technique first proposed in Wang and Chen (2002) (also see the more recent review in Wang and Su 2014) that mimics this scenario in a feedback control setting. In particular, the idea consists in monitoring and controlling the dynamics of a relatively small fraction of the nodes in the network at the microscopic level to achieve synchronization at the macroscopic level by leveraging the existing interconnections among nodes in the network.

This is achieved by introducing a *master* node whose dynamics is not affected by that of the other nodes in the network and interconnecting it to a (small) fraction of other network nodes. In so doing, agents in the network are split into two communities: those that are directly reached by the control action (also known as *pinned* nodes) and those that are not.

The closed loop network equations can then be written in the simplest case as

$$\dot{x}_i = f(x_i) + \sigma \sum_{j=1}^N \mathcal{L}_{ij} x_j + u_i, \quad i = 1, 2, \dots, M \quad (4)$$

$$\dot{x}_i = f(x_i) + \sigma \sum_{j=1}^N \mathcal{L}_{ij} x_j, \quad i = M + 1, \dots, N \quad (5)$$

where, with a slight abuse of notation, u_i is now the input through which the master node can influence the dynamics of the pinned nodes. Note that typically $M \ll N$ as the number of pinned

nodes is much smaller than the total number of agents in the network (often less than 10~20%).

The control strategy to close the loop can be chosen in a number of different ways, and many approaches have been proposed in the literature since the first appearance of the idea back in 2002. From state feedback control to adaptive, robust, switched, and hybrid control, almost all techniques have been used and tested to achieve pinning control of a complex system (for a recent review, see Wang and Su 2014). Just to illustrate one example, we take the simplest state feedback pinning control law given by setting

$$u_i = \sigma k_i (s(t) - x_i(t))$$

where $s(t)$ is the desired asymptotic collective behavior we wish the complex system to achieve and k_i is a set of control gains determining the strength of the control action on the nodes being controlled.

With this choice of control law, the closed loop equations of the complex system become

$$\dot{x}_i = f(x_i) + \sigma \left[\sum_{j=1}^N \mathcal{L}_{ij} x_j + \delta_i k_i (s(t) - x_i(t)) \right], \quad i = 1, 2, \dots, N \quad (6)$$

with δ_i being equal to 1 if node i is pinned, 0 otherwise.

A number of key questions now arise. First and foremost, how many and what nodes should be picked as those that are directly controlled? For example, do we aim at controlling the large degree nodes in the network (the hubs) or those nodes with fewer links in the network periphery? What fraction of the nodes in the network must be controlled in order to achieve convergence? Also new technical issues arise, for example, selecting the best control strategy to be used given the nonlinear dynamics of the nodes or finding the right theoretical framework to prove convergence and, if possible, estimate transient performance such as the rate of convergence toward the synchronous solution (e.g., Zhang et al. 2011).

These problems are related to the problem of studying controllability of a complex system as highlighted in Liu et al. (2011), a paper that made the cover of an issue of *Nature* in 2011. To summarize, the problem is to determine whether a complex system of interest can be controlled by exerting the control action only on a number of nodes and identify what and how many nodes to control. This problem is still an open problem in the most general case of networks of nonlinear dynamical systems and, the existing approaches can be mostly classified into two categories: those that aim at deriving graph theoretic conditions on the network structure, given the dynamics, that guarantee controllability of the associated complex system (e.g., Mesbahi and Egerstedt 2010; Liu et al. 2011) and those, often based on local approaches, that aim at finding conditions on the number of nodes and the strength of the coupling and control gains that guarantee convergence to the synchronous solution (e.g., Sorrentino et al. (2007) and Porfiri and di Bernardo (2008)). The methods proposed in Mesbahi and Egerstedt (2010) and Liu et al. (2011) and later extensions achieve the former goal, while the concept of pinning controllability first presented in Sorrentino et al. (2007) the latter. While the former set of tools relies on graph theoretic methods and the use of the theory of structural controllability, pinning controllability is studied using an extension of the semi-analytical approach known as the master stability function (MSF) in the physics literature (Pecora and Carroll 1998, 2015). Later extensions based on Lyapunov-based arguments were presented in Porfiri and di Bernardo (2008).

In all cases, it is often assumed that the network structure is static, that the node dynamics is linear or if nonlinear that it can be linearized, and that the controlled nodes can be selected at will among all nodes in the network (when this is not the case, the concept of partial controllability should be used instead; see, for example, (DeLellis et al. 2018)). So far, more complex scenarios have only been analyzed numerically. A thorough review of results on controllability of complex multi-agent systems is beyond the scope

of this entry (for further information, see Liu and Barabási 2016).

Despite their limitations, the existing tools allowed the analysis of a number of real-world scenarios finding evidence that in general only a relatively small fraction of nodes needs to be controlled and that, strikingly, in many natural and technological networks *control avoids the hubs* but tends to be localized on nodes with smaller degrees (Liu et al. 2011). This result was obtained by only looking at the structure of the graph assuming linear dynamics at the nodes. Recent studies of controllability problems for complex network systems have highlighted the importance of taking into account the control energy required to attain control and the nonlinear dynamics of the nodes (see, for instance, the results presented in Pasqualetti et al. (2014) and the recent paper by Jiang and Lai (2019)).

Still many open problems remain. For example, how to analyze controllability of time-varying network structures, or complex systems characterized by nonlinear heterogeneous systems, or those affected by noise or disturbances. Also, the problem of observability of complex systems still deserves further attention (e.g., Liu et al. 2013).

Evolving Networks and Adaptive Complex Systems

As discussed so far, the earlier models of complex systems neglected some important aspects in applications such as that agents are typically nonidentical, that the strength of the coupling and the control gains might not be the same for all edges/nodes in the network, and that the topology of the interconnections is fixed (and selected off-line). Moreover, noise or external disturbances are hardly taken into account. The pioneering work of Siljak on dynamic graphs (Siljak 1978, 2008) in the early 1970s needs to be mentioned here as one of the earlier attempts to formalize the idea of complex systems with dynamical nodes and edges (but a fixed structure) (Zecevic and Siljak 2010). Around the same time, J. Holland proposed the idea in information science of a

complex adaptive system as one adapting both its structure and dynamics to respond to environmental stimuli (Holland 1975). More recently, the concepts of adaptive networks (Gross and Sayama 2009) and evolving dynamical networks (Gorochowski et al. 2010) were proposed as a possible way forward to incorporate both aspects.

From the control viewpoint, the presence of dynamical links allows the design of distributed and decentralized adaptive strategies to control the system collective behavior, for example, toward synchronization. In this case, the network structure is still fixed, but the edges are endowed with their own adaptive dynamics which is chosen as a function of the mismatch between the dynamics of the agents they interconnect. Namely, in its simplest form, an adaptive network can be written as

$$\dot{x}_i = f(x_i) + \left[\sum_{j=1}^N \sigma_{ij}(t) \mathcal{L}_{ij} x_j \right] \quad (7)$$

where the coupling gains are now modelled by the set of time-varying functions $\sigma_{ij}(t)$ which can be selected by appropriate adaptive laws (see, for example, the strategies presented in DeLellis et al. (2009a), Lu et al. (2006), Yu et al. (2012), Das and Lewis (2012), and Kim and De Persis (2017)).

Adaptive strategies together with distributed estimation strategies of macroscopic network observables can also be used, as recently shown in Kempton et al. (2017a, b), to close the loop across scales and achieve control of macroscopic variables, such as the network connectivity or synchronizability, by acting on the edges at the microscopic level. It is also possible to consider adaptive pinning strategies able to self-tune the control and coupling gains among nodes required to achieve control (see Kempton et al. 2017a, b).

A further step is to endow the network structure with the ability of rewiring itself dynamically or evolving by adding or removing some links in order to achieve the desired control goal. This, of course, is a much harder problem that can be solved under restricting assumptions by performing off-line or online numerical optimization

(e.g., Gorochowski et al. 2010), but it is much harder to study analytically. An example of evolving strategies for controlling the collective behavior of complex systems is the *edge-snapping control technique* first proposed in DeLellis et al. (2009b). Here, the network has the same structure as in (7), but the edge dynamics is given by a nonlinear bistable dynamics driven by some function, say g , of the mismatch between the nodes at its endpoints, i.e.,

$$\ddot{\sigma}_{ij} + d\dot{\sigma}_{ij} + \frac{d}{d\sigma_{ij}} V(\sigma_{ij}) = g(x_i, x_j) \quad (8)$$

with V being a bistable potential function and d a tuning parameter that can be used to control the local transient properties of the edge dynamics.

Other more advanced approaches for the control of collective behavior in complex systems include those based on the use of multilayer and multiplex control structures such as the distributed PI strategy presented in Burbano-Lombana and di Bernardo (2015) and Lombana and Di Bernardo (2016) where the control layers implementing proportional and integral coupling among nodes can have different structures that can be exploited to enhance control performance. Other recently proposed methods include those in Scardovi et al. (2010), Seyboth et al. (2016), Liuzza et al. (2016), Montenbruck et al. (2015), and Yang and Lu (2015).

Proving Convergence

When controlling complex systems, a pressing open problem is how to prove convergence toward the desired collective behavior and certify stability, possibly globally, of the entire ensemble of interacting dynamical systems. An exhaustive review of the existing results is beyond the scope of this entry, so here I will just pinpoint some of the key approaches presented in the literature highlighting their differences.

Early attempts to prove convergence to coordinated collective behavior in networks goes back to the idea of using local methods to prove transversal stability of the synchronization

manifold. These methods are based on the master stability function (MSF) approach first presented in Pecora and Carroll (1998) which is based on linearization and block diagonalization of the network equations and the computation of the MSF defined as the magnitude of the largest Lyapunov exponent expressed as a function of a parameter encompassing information on both the network structure and the agent dynamics. Despite being a semi-analytical approach (the computation of the MSF requires the use of numerical algorithms to compute Lyapunov exponents), this method has the merit of returning conditions combining the strength of the coupling, the network structure (through the Laplacian eigenvalues), and the agent dynamics (Pecora and Carroll 2015).

Another approach often used in control theory is the use of Lyapunov-based tools yielding global but often extremely conservative results. The use of Lyapunov methods allows to deal with nonlinear vector fields, but additional conditions are required such as the QUAD condition which assumes the vector field verifies a sort of one-sided Lipschitz condition (for further details, see DeLellis et al. 2011). Other methods based on a variety of nonlinear control approaches can be found in Wieland et al. (2011), Andrieu et al. (2018), and Khong et al. (2016).

An alternative strategy to proving asymptotic stability is the use of contraction theory (Lohmiller and Slotine 1998) as explained in Slotine et al. (2004). This is particularly useful for certain types of complex systems such as biological systems where matrix measures other than the Euclidean one can be used to study the problem (Russo and Slotine 2010; Russo et al. 2010). A review with further pointers to other references can be found in di Bernardo et al. (2016).

Summary, Open Problems, and Future Directions

We have seen that many complex systems in applications can be modelled as large networks of interconnected (nonlinear) dynamical systems. The model consists of three key ingredients: a

model of the agent dynamics, a function describing the nature of the interaction among agents, and a graph capturing the structure of the interconnections among the nodes. Such systems are able to exhibit emergent properties such as synchronization, the simplest type of coordinated collective behavior often observed in natural and artificial systems.

To control the collective behavior of a complex system, we can act on each of the three aspects it comprises: we can control the nodes, the edges, or the structure itself of the node interconnections. In this entry, we reviewed some of the key approaches, particularly those based on steering the dynamics of a small fraction of the agents in the system to achieve global, macroscopic effects. We reviewed some of the existing implementations of pinning control and discussed their limitations and possible extensions.

Despite current advances, controlling collective behavior of complex systems remains a pressing open problem in many application areas, specifically, those where heterogeneity abounds such as biological networks or the network structure changes in time such as in robotics, power grids, or animal behavior. Moreover, uncertainties and noise are unavoidable in applications, and communication among nodes might take place over all sort of different media (Wi-Fi, cloud, mobile networks, etc.). Then a key challenge is how to design control strategies able to endow the system with the ability to self-organize, rewire the network of interconnections between agents in order to cope with noise, accommodate for intermittent communications or packet drops, and achieve the desired control goal. Also recently, it has been pointed out that, intriguingly, noise can be beneficial to control the collective behavior of a complex system (see, for example, Russo and Shorten 2018 and Burbano-L et al. 2017).

Ultimately, the goal is to go beyond synchronization toward other more complex types of coordinated collective behavior and devise strategies to mimic natural complex systems, such as school of fish or flocks of birds, that are able to perform collective maneuvers at relatively high speeds with limited communication and in the absence of any centralized intelligence.

These systems are characterized by the ability to evolve and self-organize, changing their structure to accommodate environmental changes. A hurdle for control system design is the lack of a theoretical framework to prove convergence in these scenarios, particularly those where the agents are strongly heterogeneous or stochastic, noise is present, and the agents are strongly nonlinear or even hybrid or discontinuous.

This is an area full of opportunities for exciting research. If we succeed, we can mimic natural systems and design self-organizing, robust, and flexible control strategies for complex multi-agent systems. In so doing, we will be able to take control into new emerging applications such as those coming from biology and health or swarm robotics where thousands of individual cells or microrobots need to finely coordinate their collective behavior in order to achieve the desired control goal.

Cooperative Manipulators

Fabrizio Caccavale

School of Engineering, Università degli Studi della Basilicata, Viale dell'Ateneo Lucano 10, Potenza, Italy

Abstract

This chapter presents an overview of the main modeling and control issues related to cooperative manipulation of a common object by means of two or more robotic manipulators. A historical path is followed to present the main research results on cooperative manipulation. Kinematics and dynamics of robotic arms cooperatively manipulating a tightly grasped rigid object are briefly discussed. Then, the main strategies for force/motion control of cooperative systems are briefly reviewed.

Keywords

Cooperative task space · Coordinated motion · Force/motion control · Grasping · Manipulation · Multi-arm systems

Introduction

Since the early 1970s, it has been recognized that many tasks, which are difficult or even impossible to execute by a single robotic manipulator, become feasible when two or more manipulators work in a cooperative way. Examples of typical cooperative tasks are the manipulation of heavy and/or large payloads, assembly of multiple parts, and handling of flexible and articulated objects. (see Fig. 1 for an example of cooperative robotic work cell).

In the 1980s research achieved several theoretical results related to modeling and control of single-arm robots; this further fostered research on multi-arm robotic systems. Dynamics and control as well as force control issues have been widely explored along the decade.

Cooperative

Manipulators, Fig. 1 An example of a cooperative robotic work cell composed by two industrial robot arms

C

In the 1990s parametrization of the constraint forces/moments acting on the object has been recognized as a key to solving control problems and has been studied in several papers (see, e.g., contributions in Uchiyama and Dauchez 1993; Walker et al. 1991; Williams and Khatib 1993, and Sang et al. 1995). Several control schemes for cooperative manipulators based on the sought parameterizations have been designed, including force/motion control (Wen and Kreutz-Delgado 1992) and impedance control (Schneider and Cannon 1992; Bonitz and Hsia 1996). Other approaches are adaptive control (Hu et al. 1995), kinematic control (Chiacchio et al. 1996), task-space regulation (Caccavale et al. 2000), and model-based coordinated control (Hsu 1993). Other important topics investigated in the 1990s were the definition of user-oriented task-space variables for coordinated control (Chiacchio et al. 1996; Caccavale et al. 2000), the development of meaningful performance measures (Chiacchio et al. 1991a,b) for multi-arm systems, and the problem of load sharing (Walker et al. 1989).

Most of the abovementioned works assume that the cooperatively manipulated object is rigid and tightly grasped. However, since 1990s, several research efforts have been focused on the control of cooperative flexible manipulators (Yamano et al. 2004), since flexible-arm robots merits (lightweight structure, intrinsic compliance, and hence safety) can be conveniently exploited in cooperative manipulation. Other research efforts have been focused

on the control of cooperative systems for the manipulation of flexible objects (Yukawa et al. 1996) and, more recently, on the cooperative transportation and manipulation of objects via multiple mobile robotic system (Khatib et al. 1996; Sugar and Kumar 2002; Bai and Wen 2010).

Modeling, Load Sharing, and Performance Evaluation

The first modeling goal is the definition of suitable variables describing the kinetostatics of a cooperative system. Hereafter, the main results available are summarized for a dual-arm system composed by two cooperative manipulators grasping a common object.

The kinetostatic formulation proposed by Uchiyama and Dauchez (1993), i.e., the so-called symmetric formulation, is based on kinematic and static relationships between generalized forces/velocities acting at the object and their counterparts acting at the manipulators end effectors. To this aim, the concept of *virtual stick* is defined as the vector which determines the position of an object-fixed coordinate frame with respect to the frame attached to each robot end effector (Fig. 2). When the object grasped by the two manipulators can be considered rigid and tightly attached to each end effector, then the virtual stick behaves as a rigid stick fixed to each end effector. According to the

Cooperative Manipulators, Fig. 2 Grasp geometry for a two-manipulator cooperative system manipulating a common object. The vectors $\mathbf{r}_1$ and $\mathbf{r}_2$ are the *virtual sticks*, $\mathcal{T}_c$ is the coordinate frame attached to the object, and $\mathcal{T}_1$ and $\mathcal{T}_2$ are the coordinate frames attached to each end effector

symmetric formulation, the vector, $\mathbf{h}$, collecting the generalized forces (i.e., forces and moments) acting at each end effector is given by:

$$\mathbf{h} = \mathbf{W}^\dagger \mathbf{h}_E + \mathbf{V} \mathbf{h}_I, \quad (1)$$

where $\mathbf{W}$ is the so-called grasp matrix; the columns of $\mathbf{V}$ span the null space of the grasp matrix; $\mathbf{h}_I$ is the generalized force vector which does not contribute to the object's motion, i.e., it represents internal loading of the object (mechanical stresses) and is termed as *internal forces*; while $\mathbf{h}_E$ represents the vector of *external forces*, i.e., forces and moments causing the object's motion. Later, a *task-oriented formulation* has been proposed (Chiacchio et al. 1996), aimed at defining a *cooperative task space* in terms of *absolute* and *relative* motion of the cooperative system, which can be directly computed from the position and orientation of the end-effector coordinate frames.

The dynamics of a cooperative multi-arm system can be written as the dynamics of the single manipulators together with the closed-chain constraints imposed by the grasped object.

By eliminating the constraints, a reduced-order model can be obtained (Koivo and Unseren 1991).

Strongly related to kinetostatics and dynamics of cooperative manipulators is the load sharing problem, i.e., distributing the load among the arms composing the system (Walker et al. 1989). A very relevant problem related to the load sharing is that of robust holding, i.e., the problem of determining forces/moments applied to object by the arms, in order to keep the grasp even in the presence of disturbing forces/moments (Uchiyama and Yamashita 1991).

A major issue in robotic manipulation is the performance evaluation via suitably defined indexes (e.g., manipulability ellipsoids). These concepts have been extended to multi-arm robotic systems in Chiacchio et al. (1991a,b). Namely, by exploiting the kinetostatic formulations described above, velocity and force manipulability ellipsoids can be defined, by regarding the whole cooperative system as a mechanical transformer from the joint space to the cooperative task space. The manipulability ellipsoids can be seen as performance measures aimed at determining the attitude of the system to cooperate in a given configuration.

Finally, it is worth mentioning the strict relationship between problems related to grasping of objects by fingers/hands and those related to cooperative manipulation. In fact, in both cases, multiple manipulation structures grasp a commonly manipulated object. In multifingered hands only some motion components are transmitted through the contact point to the manipulated object (unilateral constraints), while cooperative manipulation via robotic arms is achieved by rigid (or near-rigid) grasp points, and interaction takes place by transmitting all the motion components through the grasping points (bilateral constraints). While many common problems between the two fields can be tackled in a conceptually similar way (e.g., kinetostatic modeling, force control), many others are specific of each of the two application fields (e.g., form and force closure for multifingered hands).

Control

When a cooperative multi-arm system is employed for the manipulation of a common object, it is important to control both the absolute motion of the object and the internal stresses applied to it. Hence, most of the control approaches to cooperative robotic systems can be classified as force/motion control schemes.

Early approaches to the control of cooperative systems were based on the *master/slave* concept. Namely, the cooperative system is decomposed in a position-controlled master arm, in charge of imposing the absolute motion of the object, and the force-controlled slave arms, which are to follow (as smoothly as possible) the motion imposed by the master. A natural evolution of the above-described concept has been the so-called *leader/follower* approach, where the follower arms reference motion is computed via closed-chain constraints. However, such approaches suffered from implementation issues, mainly due to the fact that the compliance of the slave arms has to be very large, so as to smoothly follow the motion imposed by the master arm. Moreover, the roles of master and slave (leader and follower) may need to be changed during the task execution.

Due to the abovementioned limitations, more natural non-master/slave approaches have been pursued later, where the cooperative system is seen as a whole. Namely, the reference motion of the object is used to determine the motion of all the arms in the system, and the interaction forces are measured and fed back so as to be directly controlled. To this aim, the mappings between forces and velocities at the end effector of each manipulator and their counterparts at the manipulated object are considered in the design of the control laws.

An approach, based on the classical hybrid force/position control scheme, has been proposed in Uchiyama and Dauchez (1993), by exploiting the symmetric formulation described in the previous section.

In Wen and Kreutz-Delgado (1992) a Lyapunov-based approach is pursued to devise force/position PD-type control laws. Namely, the

joints torques inputs to each arm are computed as the combination of two contributions:

$$\tau_m = \tau_p + \tau_h, \quad (2)$$

where τ_p is a PD-type term (eventually including a feedback/feedforward model-based compensation term), taking care of position control, while τ_h is in charge of internal forces/moments control. This approach has been extended in Caccavale et al. (2000), where kinetostatic filtering of the control action is performed, so as to eliminate all the components of the control input which contribute to internal stresses at the object.

A further improvement of the PD plus gravity compensation control approach has been achieved by introducing a full model compensation, so as to achieve feedback linearization of the closed loop system. The feedback linearization approach formulated at the operational space level is the base of the so-called *augmented object* approach (Sang et al. 1995). In this approach the system is modeled in the operational space as a whole, by suitably expressing its inertial properties via a single augmented inertia matrix M_O , i.e.,

$$M_O(x_E)\ddot{x}_E + c_O(x_E, \dot{x}_E) + g_O(x_E) = h_E. \quad (3)$$

where M_O , c_O , and g_O are the operational space terms modeling, respectively, the inertial properties of the whole system (manipulators and object); the Coriolis, centrifugal, and friction terms; and the gravity terms, while x_E is the operational space vector describing the position and orientation of the coordinate frame attached to the grasped object. In the framework of feedback linearization (formulated in the operational space), the problem of controlling the internal forces can be solved, e.g., by resorting to the *virtual linkage* model (Williams and Khatib 1993) or according to the scheme proposed in Hsu (1993), i.e.,

$$\tau_m = J^T W^\dagger [M_O(\ddot{x}_{E,d} + K_v \dot{e}_E + K_p e_E) + c_O + g_O] + J^T V \left(h_{I,d} + K_h \int e_{h,I} \right), \quad (4)$$

where the subscript “d” denotes the desired variables; $\mathbf{e}_E$ is the tracking error computed in terms of object’s position/orientation variables; $\mathbf{e}_{h,i}$ is the internal force tracking error; $\mathbf{K}_p$, $\mathbf{K}_v$, and $\mathbf{K}_h$ are positive-definite matrix gains; and $\mathbf{J}$ is a block-diagonal matrix collecting the individual Jacobian matrices of the manipulators; the above control law yields a linear and decoupled closed-loop dynamics, such that motion and force tracking errors asymptotically vanish.

An alternative control approach is based on the well-known impedance concept (Schneider and Cannon 1992; Bonitz and Hsia 1996). In fact, when a manipulation system interacts with an external environment and/or other manipulators, large values of the contact forces and moments can be avoided by enforcing a compliant behavior with suitable dynamic features. In detail, the following mechanical impedance behavior between the object displacements and the forces due to the object-environment interaction can be enforced (*external impedance*):

$$\mathbf{M}_E \tilde{\mathbf{a}}_E + \mathbf{D}_E \tilde{\mathbf{v}}_E + \mathbf{K}_E \mathbf{e}_E = \mathbf{h}_{env}, \quad (5)$$

where $\mathbf{e}_E$ represents the vector of displacements between object’s desired and actual pose, $\tilde{\mathbf{v}}_E$ is the difference between the object’s desired and actual velocities, $\tilde{\mathbf{a}}_E$ is the difference between the object’s desired and actual accelerations, and $\mathbf{h}_{env}$ is the generalized force acting on the object, due to the interaction with the environment. The impedance dynamics is characterized in terms of given positive definite mass, damping, and stiffness matrices ($\mathbf{M}_E$, $\mathbf{D}_E$, $\mathbf{K}_E$). A mechanical impedance behavior between the i th end-effector displacements and the internal forces can be imposed as well (*internal impedance*):

$$\mathbf{M}_{I,i} \tilde{\mathbf{a}}_i + \mathbf{D}_{I,i} \tilde{\mathbf{v}}_i + \mathbf{K}_{I,i} \mathbf{e}_i = \mathbf{h}_{I,i}, \quad (6)$$

where $\mathbf{e}_i$ is the vector expressing the displacement between the commanded and the actual pose of the i th end effector, $\tilde{\mathbf{v}}_i$ is the vector expressing the difference between commanded and actual velocities of the i th end effector, $\tilde{\mathbf{a}}_i$ is the vector expressing the difference between commanded and actual accelerations of the i th

end effector, and $\mathbf{h}_{I,i}$ is the contribution of the i th end effector to the internal force. Again, the impedance dynamics is characterized in terms of given positive definite mass, damping, and stiffness matrices ($\mathbf{M}_{I,i}$, $\mathbf{D}_{I,i}$, $\mathbf{K}_{I,i}$). An impedance scheme designed to control of both external forces and internal forces has been developed in Caccavale et al. (2008).

Summary and Future Directions

This entry provides a brief survey of the main issues related to cooperative robots, with special emphasis on modeling and control problems. Among several open research topics in cooperative manipulation, it is worth mentioning the problem of cooperative transportation and manipulation of objects via multiple mobile manipulators. In fact, although notable results have been already devised in Khatib et al. (1996), Sugar and Kumar (2002), and Bai and Wen (2010), the foreseen use of robotic teams in industrial settings (hyperflexible robotic work cells) and/or in collaboration with humans (robotic coworker concept) raises new challenges related to autonomy and safety of multiple mobile manipulators. Also, an emerging application field is given by cooperative systems composed by multiple aerial vehicle-manipulator systems (see, e.g., Fink et al. 2011).

Abstract

This article presents the fundamental elements of the theory of cooperative games in the context of dynamic systems. The concepts of Pareto optimality, Nash bargaining solution, characteristic function, cores,

and C-optimality are discussed, and some fundamental results are recalled.

Keywords

Cores · Nash equilibrium · Pareto optimality

Introduction

Solution concepts in game theory are regrouped in two main categories called noncooperative and cooperation solutions, respectively. In the seminal book of von Neumann and Morgenstern (1944) this categorization is already made. These authors discuss zero-sum (matrix) games in normal form, where the noncooperative solution concept of saddle-point was defined and characterized, and games in characteristic function form, where solution concepts for games of coalitions were introduced. In this article we present the fundamental solution concepts of the theory of cooperative games in the context of dynamical systems. The article is organized as follows: we first recall the papers, which mark the origin of development of a theory of dynamic games; then we recall the basic concept of Pareto optimality proposed as a cooperative solution concept; we present the scalarization technique and the necessary or sufficient optimality conditions for Pareto optimality in mathematical programming and optimal control settings; we then explore the difficulties encountered when one tried to extend the Nash bargaining solution, characteristic function and cores concept to dynamic games; we show the links that exist with the theory of reachability for perturbed dynamic systems.

The Origins

One may consider that the first introduction of a cooperative game solution concept in systems and control science is due to L.A. Zadeh (1963). Two-player zero-sum dynamic games have been studied by R. Isaacs (1954) in a deterministic continuous time setting and by L. Shapley (1953)

in a discrete time stochastic setting. Nonzero-sum and m player differential games were introduced by Y.C. Ho and A.W. Starr (1969) and J.H. Case (1969). For these games cooperative solutions can be looked for to complement the noncooperative Nash equilibrium concept.

Cooperation Solution Concept

In cooperative games one is interested in nondominated solution. This solution type is related to a concept introduced by the well-known economist V. Pareto (1869) in the context of welfare economics. Consider a system with decision variables $x \in X \subset \mathbb{R}^n$ and m performance criteria $x \rightarrow \psi_j(x) \in \mathbb{R}$, $j = 1, \dots, m$ that one tries to maximize.

Definition 1 The decision $x^* \in X$ is nondominated or Pareto optimal if the following condition holds:

$$\begin{aligned} \psi_j(x) &\geq \psi_j(x^*) \quad \forall j = 1, \dots, m \\ \implies \psi_j(x) &= \psi_j(x^*) \quad \forall j = 1, \dots, m. \end{aligned}$$

In other words it is impossible to give one criterion j a value greater than $\psi_j(x^*)$ without decreasing the value of another criterion, say ℓ , which then takes a value lower than $\psi_\ell(x^*)$.

This vector-valued optimization framework corresponds to a situation where m players are engaged in a game, described in its normal form, where the strategies of the m players constitute the decision vector x and their respective payoffs are given by the m performance criteria $\psi_j(x)$, $j = 1, \dots, m$. One assumes that these players jointly take a decision that is cooperatively optimal, in the sense that no player can improve his/her payoff without deteriorating the payoff of at least one other player.

The Scalarization Technique

Let $\mathbf{r} = (r_1, r_2, \dots, r_m)$ be a given m -vector composed of normalized weights that satisfy $r_j > 0$, $j = 1, \dots, m$ and $\sum_{j=1, \dots, m} r_j = 1$.

Lemma 1 Let $x^* \in X$ be a maximum in X for the scalarized criterion $\Psi(x; \mathbf{r}) = \sum_{j=1}^m r_j \psi_j(x)$. Then x^* is a nondominated solution for the multi-objective problem.

The proof is very simple. Suppose x^* is dominated, then there exists $x^\circ \in X$ such that $\psi_j(x^\circ) \geq \psi_j(x^*)$, $\forall j = 1, \dots, m$, and $\psi_i(x^\circ) > \psi_i(x^*)$ for one $i \in \{1, \dots, m\}$. Since all the r_j are > 0 , this yields $\sum_{j=1}^m r_j \psi_j(x^\circ) > \sum_{j=1}^m r_j \psi_j(x^*)$, which contradicts the maximizing property of x^* . This result shows that it will be very easy to find many Pareto optimal solutions by varying a strictly positive weighting of the criteria. But this procedure will not find all of the nondominated solutions.

Conditions for Pareto Optimality in Mathematical Programming

N.O. Da Cunha and E. Polak (1967b) have obtained the first necessary conditions for multi-objective optimization. The problem they consider is

$$\begin{aligned} &\text{Pareto Opt. } \psi_j(x) \quad j = 1, \dots, m \\ &\text{s.t.} \\ &\varphi_k(x) \leq 0 \quad k = 1, \dots, p \end{aligned}$$

where the functions $x \in \mathbb{R}^n \mapsto \psi_j(x) \in \mathbb{R}$, $j = 1, \dots, m$, and $x \mapsto \varphi_k(x) \in \mathbb{R}$, $k = 1, \dots, p$ are continuously differentiable (C^1) and where we assume that the constraint qualification conditions of mathematical programming hold for this problem too. They proved the following theorem.

Theorem 1 Let x^* be a Pareto optimal solution of the problem defined above. Then there exists a vector λ of p multipliers λ_k , $k = 1, \dots, p$, and a vector $\mathbf{r} \neq 0$ of m weights $r_j \geq 0$, such that the following conditions hold

$$\begin{aligned} \frac{\partial}{\partial x} \mathcal{L}(x^*; \mathbf{r}; \lambda) &= 0 \\ \varphi_k(x^*) &\leq 0 \\ \lambda_k \varphi_k(x^*) &= 0 \\ \lambda_k &\geq 0, \end{aligned}$$

where $\mathcal{L}(x^*; \mathbf{r}; \lambda)$ is the weighted Lagrangian defined by

$$\mathcal{L}(x; \mathbf{r}; \lambda) = \sum_{j=1}^m r_j \psi_j(x) + \sum_{k=1}^p \lambda_k \varphi_k(x).$$

So there is a local scalarization principle for Pareto optimality.

Maximum Principle

The extension of Pareto optimality concept to control systems was done by several authors (Binmore et al. 1986; Zadeh 1963; Basile and Vincent 1970; Vincent and Leitmann 1970; Salukvadze 1971; Leitmann et al. 1972; Blaqui re et al. 1972; Bellassali and Jourani 2004), the main result being an extension of the maximum principle of Pontryagin. Let a system be governed by state equations:

$$\dot{x}(t) = f(x(t), u(t)) \quad (1)$$

$$u(t) \in U \quad (2)$$

$$x(0) = x_0 \quad (3)$$

$$t \in [0, T] \quad (4)$$

where $x \in \mathbb{R}^n$ is the state variable of the system, $u \in U \subset \mathbb{R}^p$ with U compact is the control variable, and $[0, T]$ is the control horizon. The system is evaluated by m performance criteria of the form

$$\psi_j(x(\cdot), u(\cdot)) = \int_0^T g_j(x(t), u(t)) dt + G_j(x(T)), \quad (5)$$

for $j = 1, \dots, m$. Under the usual assumptions of control theory, i.e., $f(\cdot, \cdot)$ and $g_j(\cdot, \cdot)$, $j = 1, \dots, m$, being C^1 in x and continuous in u , $G_j(\cdot)$ being C^1 in x , one can prove the following.

Theorem 2 Let $\{x^*(t) : t \in [0, T]\}$ be a Pareto optimal trajectory, generated at initial state x° by the Pareto optimal control $\{u^*(t) : t \in [0, T]\}$. Then there exist costate vectors $\{\lambda^*(t) : t \in [0, T]\}$ and a vector of positive weights $\mathbf{r} \neq 0 \in \mathbb{R}^m$, with components $r_j \geq 0$, $\sum_{j=1}^m r_j = 1$, such that the following relations hold:

$$\dot{x}^*(t) = \frac{\partial}{\partial \lambda} H(x^*(t), u^*(t); \lambda(t); \mathbf{r}) \quad (6)$$

$$\dot{\lambda}(t) = -\frac{\partial}{\partial x} H(x^*(t), u^*(t); \lambda(t); \mathbf{r}) \quad (7)$$

$$x^*(0) = x_o \quad (8)$$

$$\lambda(T) = \sum_{j=1}^m r_j \frac{\partial}{\partial x} G_j(x(T)) \quad (9)$$

with

$$\begin{aligned} & H(x^*(t), u^*(t); \lambda(t); \mathbf{r}) \\ &= \max_{u \in U} H(x^*(t), u; \lambda(t); \mathbf{r}) \end{aligned}$$

where the weighted Hamiltonian is defined by

$$H(x, u; \lambda; \mathbf{r}) = \sum_{j=1}^m r_j g_j(x, u) + \lambda^T f(x, u).$$

The proof of this result necessitates some additional regularity assumptions. Some of these conditions imply that there exist differentiable Bellman value functions (see, e.g., Blaquièrre et al. 1972); some others use the formalism of nonsmooth analysis (see, e.g., Bellassali and Jourani 2004).

The Nash Bargaining Solution

Since Pareto optimal solutions are numerous (actually since a subset of Pareto outcomes are indexed over the weightings $\mathbf{r}$, $r_j > 0$, $\sum_{j=1}^m r_j = 1$), one can expect, in the payoff m -dimensional space, to have a manifold of Pareto outcomes. Therefore, the problem that we must solve now is *how to select the “best” Pareto outcome?* “Best” is a misnomer here, because, by their very definition, two Pareto outcomes cannot be compared or gauged. The choice of a Pareto outcome that satisfies each player must be the result of some bargaining. J. Nash addressed this problem very early, in 1951, using a two-player game setting. He developed an axiomatic approach where he proposed four behavior axioms which, if accepted, would determine a

unique choice for the bargaining solution. These axioms are called respectively, (i) invariance to affine transformations of utility representations, (ii) Pareto optimality, (iii) independence of irrelevant alternatives, and (iv) symmetry. Then the bargaining point is the Pareto optimal solution that maximizes the product

$$x^* = \operatorname{argmax}_x (\psi_1(x) - \psi_1(x^\circ))(\psi_2(x) - \psi_2(x^\circ))$$

where x° is the status quo decision, in case bargaining fails, and $(\psi_j(x^\circ))$, $j = 1, 2$ are the payoffs associated with this no-accord decision (this defines the so-called threat point). It has been proved (Binmore et al. 1986) that this solution could be obtained also as the solution of an auxiliary dynamic game in which a sequence of claims and counterclaims is made by the two players when they bargain.

When extended directly to the context of differential or multistage games, the Nash bargaining solution concept proved to lack the important property of time consistency. This was first noticed in Haurie (1976). Let a dynamic game be defined by Eqs. (1)–(5), with $j = 1, 2$. Suppose the status quo decision, if no agreement is reached at initial state ($t = 0$, $x(0) = x^\circ$), consists in playing an open-loop Nash equilibrium, defined by the controls $u_j^N(\cdot) : [0, T] \rightarrow U_j$, $j = 1, 2$ and generating the trajectory $x^N(\cdot) : [0, T] \rightarrow \mathbb{R}^n$, with $x^N(0) = x_o$. Now applying the Nash bargaining solution scheme to the data of this differential game played at time $t = 0$ and state $x(0) = x_o$, one identifies a particular Pareto optimal solution, associated with the controls $u^*(\cdot) : [0, T] \rightarrow U_j$, $j = 1, 2$ and generating the trajectory $x^*(\cdot) : [0, T] \rightarrow \mathbb{R}^n$, with $x^*(0) = x_o$. Now assume the two players renegotiate the agreement to play $u_j^*(\cdot)$ at an intermediate point of the Pareto optimal trajectory $(\tau, x^*(\tau))$, $\tau \in (0, T)$. When computed from that point, the status quo strategies are in general not the same as they were at $(0, x_o)$; furthermore, the shape of the Pareto frontier, when the game is played from $(\tau, x^*(\tau))$, is different from what it is when the game is played at $(0, x_o)$. For these two reasons the bargaining solution at $(\tau, x^*(\tau))$

will not coincide in general with the restriction to the interval $[\tau, T]$ of the bargaining solution from $(0, x_0)$. This implies that the solution concept is not *time consistent*. Using feedback strategies, instead of open-loop ones, does not help, as the same phenomena (change of status quo and change of Pareto frontier) occur in a feedback strategy context.

This shows that the cooperative game solutions proposed in the classical theory of games cannot be applied without precaution in a dynamic setting when players have the possibility to renegotiate agreements at any intermediary point $(t, x^*(t))$ of the bargained solution trajectory.

Cores and C-Optimality in Dynamic Games

Characteristic functions and the associated solution concept of core are important elements in the classical theory of cooperative games. In two papers (Haurie and Delfour 1974; Haurie 1975) the basic definitions and properties of the concept of core in dynamic cooperative games were presented. Consider the multistage system, controlled by a set M of m players and defined by

$$\begin{aligned} x(k+1) &= f^k(x(k), u_M(k)), \\ k &= 0, 1, \dots, K-1 \\ x(i) &= x^i, \quad i \in \{0, 1, \dots, K-1\} \\ u_M(k) &\triangleq (u_j(k))_{j \in M} \in U_M(k) \triangleq \prod_{j \in M} U_j(k). \end{aligned}$$

From the initial point (i, x^i) a control sequence $(u_M(i), \dots, u_M(K-1))$ generates for each player j a payoff defined as follows:

$$\begin{aligned} J_j(i, x^i; u_M(i), \dots, u_M(K-1)) &\triangleq \\ \sum_{k=i}^{K-1} \Phi_j(x(k), u_M(k)) &+ \Upsilon_j(x(K)). \end{aligned}$$

A subset S of M is called a coalition. Let $\mu_S^k : x(k) \mapsto u_S(k) \in \prod_{j \in S} U_j(k)$ be a feedback control for the coalition defined at each stage k . A player $j \in S$ considers then, from any initial point (i, x^i) , his guaranteed payoff:

$$\begin{aligned} \Psi_j(i, x^i; \mu_S^i, \dots, \mu_S^{K-1}) &\triangleq \\ \inf_{u_{M-S}(i) \in U_{M-S}(i), \dots, u_{M-S}(K-1) \in U_{M-S}(K-1)} & \\ \sum_{k=i}^{K-1} \Phi_j(x(k), [\mu_S^k(x(k)), u_{M-S}(k)]) & \\ + \Upsilon_j(x(K)). & \end{aligned}$$

Definition 2 The characteristic function at stage i for coalition $S \subset M$ is the mapping $v^i : (S, x^i) \mapsto v^i(S, x^i) \subset \mathbb{IR}^S$ defined by

$$\begin{aligned} \omega_S &\triangleq (\omega_j)_{j \in S} \in v^i(S, x^i) \Leftrightarrow \\ \exists \mu_S^i, \dots, \mu_S^{K-1} : \forall j \in S & \\ \Psi_j(i, x^i; \mu_S^i, \dots, \mu_S^{K-1}) &\geq \omega_j. \end{aligned}$$

In other words, there is a feedback law for the coalition S which guarantees at least ω_j to each player j in the coalition.

Suppose that in a cooperative agreement, at point (i, x^i) , the coalition S is proposed a gain vector ω_S which is interior to $v^i(S, x^i)$. Then coalition S will block this agreement, because using an appropriate feedback, the coalition can guarantee a better payoff to each of its members. We can now extend the definition of the core of a cooperative game to the context of dynamic games, as the set of agreement gains that cannot be blocked by any coalition.

Definition 3 The core $\Omega(i, x^i)$ at point (i, x^i) is the set of gain vectors $\omega_M \triangleq (\omega_j)_{j \in M}$ such that:

1. There exists a Pareto optimal control $u_M^*(i), \dots, u_M^*(K-1)$ for which $\omega_j = J_j(i, x^i; u_M^*(i), \dots, u_M^*(K-1))$,
2. $\forall S \subset M$ the projection of ω_M in $\mathbb{IR}^S$ is not interior to $v^i(S, x^i)$

Playing a cooperative game, one would be interested in finding a solution where the gain-to-go remains in the core at each point of the trajectory. This leads us to define the following.

Definition 4 A control $\tilde{u}^o \triangleq (u_M^o(0), \dots, u_M^o(K-1))$ is C -optimal at $(0, x^0)$ if $\tilde{u}^o$ is Pareto optimal generating a state trajectory

$$\{x^o(0) = x^0, x^o(1), \dots, x^o(K)\}$$

and a sequence of gain-to-go values

$$\begin{aligned} \omega_j^o(i) &= J_j(i, x^o(i); u_M^o(i), \dots, u_M^o(K-1)), \\ i &= 0, \dots, K-1 \end{aligned}$$

such that $\forall i = 0, 1, \dots, K-1$, the m -vector $\omega_M^o(i)$ is element of the core $\Omega(i, x^o(i))$.

A C -optimal control generates an agreement which cannot be blocked by any coalition along the Pareto optimal trajectory. It can be shown on examples that a Pareto optimal trajectory which has the gain-to-go vector in the core at initial point $(0, x_0)$ is not C -optimal.

Links with Reachability Theory for Perturbed Systems

The computation of characteristic functions can be made using the techniques developed to study reachability of dynamic systems with set constrained disturbances (see Bertsekas and Rhodes 1971). Consider the particular case of a linear system

$$x(k+1) = A^k x(k) + \sum_{j \in M} B_j^k u_j(k) \quad (10)$$

where $x \in \mathbb{R}^n$, $u_j \in U_j^k \subset \mathbb{R}^{p_j}$, where U_j^k is a convex-bound set and A^k, B_j^k are matrices of appropriate dimensions. Let the payoff to player j be defined by:

$$\begin{aligned} J_j(i, x^i; u_M(i), \dots, u_M(K-1)) &\triangleq \\ \sum_{k=i}^{K-1} \phi_j^k(x(k)) + \gamma_j^k(u_j(k)) + \Upsilon_j(x(K)). \end{aligned}$$

Algorithm Here we use the notations $\phi_S^k \triangleq (\phi_j^k)_{j \in S}$ and $B_S^k u_S \triangleq \sum_{j \in S} B_j^k u_j$. Also we denote $\{u + V\}$, where u is a vector in $\mathbb{R}^m$ and $V \subset \mathbb{R}^m$, the set of vectors $u + v$, $\forall v \in V$. Then

1. $\forall x^K v^K(S, x^K) \triangleq \{\omega_S \in \mathbb{R}^S : \Upsilon_S(x^K) \geq \omega_S\}$
2. $\forall x \mathcal{E}^{k+1}(S, x) \triangleq \cap_{v \in U_{M-S}} v^{k+1}(S, x + B_{M-S}^k v)$
3. $\forall x^k \mathcal{H}^k(S, x^k) \triangleq \bigcup_{u \in U_S} \{\gamma_S^k(u) + \mathcal{E}^{k+1}(S, A^k x^k + B_S^k u)\}$
4. $\forall x^k v^k(S, x^k) = \{\phi_S^k(x^k) + \mathcal{H}^k(S, x^k)\}.$

In an open-loop control setting, the calculation of characteristic function can be done using the concept of Pareto optimal solution for a system with set constrained disturbances, as shown in Goffin and Haurie (1973, 1976) and Haurie (1973).

Conclusion

Since the foundations of a theory of cooperative solutions to dynamic games, recalled in this article, the research has evolved toward the search for cooperative solutions that could be also equilibrium solution, using for that purpose a class of memory strategies Haurie and Towinski (1985), and has found a very important domain of application in the assessment of environmental agreements, in particular those related to the climate change issue. For example, the sustainability of solutions in the core of a dynamic game modeling international environmental negotiations is studied in Germain et al. (2003). A more encompassing model of dynamic formation of coalitions and stabilization of solutions through the use of threats is proposed in Breton et al. (2010). These references are indicative of the trend of research in this field.

Coordination of Distributed Energy Resources for Provision of Ancillary Services: Architectures and Algorithms

Alejandro D. Domínguez-García¹ and Christoforos N. Hadjicostis²

¹University of Illinois at Urbana-Champaign, Urbana-Champaign, IL, USA

²Department of Electrical and Computer Engineering, University of Cyprus, Nicosia, Cyprus

Abstract

We discuss the utilization of distributed energy resources (DERs) to provide active and reactive power support for ancillary services. Though the amount of active and/or

reactive power provided individually by each of these resources can be very small, their presence in large numbers in power distribution networks implies that, under proper coordination mechanisms, they can collectively provide substantial active and reactive power regulation capacity. In this entry, we provide a simple formulation of the DER coordination problem for enabling their utilization to provide ancillary services. We also provide specific architectures and algorithmic solutions to solve the DER coordination problem, with focus on decentralized solutions.

Ancillary services · Consensus · Distributed algorithms · Distributed energy resources (DERs)

Introduction

On the distribution side of a power system, there are many distributed energy resources (DERs), e.g., photovoltaic (PV) installations, plug-in hybrid electric vehicles (PHEVs), and thermostatically controlled loads (TCLs), that can be potentially used to provide ancillary services, e.g., reactive power support for voltage control (see, e.g., Turitsyn et al. (2011) and the references therein) and active power up and down regulation for frequency control (see, e.g., Callaway and Hiskens (2011) and the references therein). To enable DERs to provide ancillary services, it is necessary to develop appropriate control and coordination mechanisms. One potential solution relies on a centralized control architecture in which each DER is directly coordinated by (and communicates with) a central decision maker. An alternative approach is to distribute the decision making, which obviates the need for a central decision maker to coordinate the DERs. In both cases, the decision making involves solving a

resource allocation problem for coordinating the DERs to collectively provide a certain amount of a resource (e.g., active or reactive power).

In a practical setting, whether a centralized or a distributed architecture is adopted, the control of DERs for ancillary services provision will involve some aggregating entity that will gather together and coordinate a set of DERs, which will provide certain amount of active or reactive power in exchange for monetary benefits. In general, these aggregating entities are the ones that interact with the ancillary services market, and through some market-clearing mechanism, they enter a contract to provide some amount of resource, e.g., active and/or reactive power over a period of time. The goal of the aggregating entity is to provide this amount of resource by properly coordinating and controlling the DERs, while ensuring that the total monetary compensation to the DERs for providing the resource is below the monetary benefit that the aggregating entity obtains by selling the resource in the ancillary services market.

In the context above, a household with a solar PV rooftop installation and a PHEV might choose to offer the PV installation to a renewable aggregator so it is utilized to provide reactive power support (this can be achieved as long as the PV installation power electronics-based grid interface has the correct topology Domínguez-García et al. 2011). Additionally, the household could offer its PHEV to a battery vehicle aggregator to be used as a controllable load for energy peak shaving during peak hours and load leveling at night (Guille and Gross 2009). Finally, the household might choose to enroll in a demand response program in which it allows a demand response provider to control its TCLs to provide frequency regulation services (Callaway and Hiskens 2011). In general, the renewable aggregator, the battery vehicle aggregator, and the demand response provider can be either separate entities or they can be the same entity. In this entry, we will refer to these aggregating entities as *aggregators*.

The Problem of DER Coordination

Without loss of generality, denote by x_j the amount of resource provided by DER i without specifying whether it is active or reactive power. [However, it is understood that each DER provides (or consumes) the same type of resource, i.e., all the x_i 's are either active or reactive power.] Let $0 < \underline{x}_i < \bar{x}_i$, for $i = 1, 2, \dots, n$, denote the minimum ($\underline{x}_i$) and maximum ($\bar{x}_i$) capacity limits on the amount of resource x_i that node i can provide. Denote by X the total amount of resource that the DERs must collectively provide to satisfy the aggregator request. Let $\pi_i(x_i)$ denote the price that the aggregator pays DER i per unit of resource x_i that it provides. Then, the objective of the aggregator in the DER coordination problem is to minimize the total monetary amount to be paid to the DERs for providing the total amount of resource X while satisfying the individual capacity constraints of the DERs. Thus, the DER coordination problem can be formulated as follows:

$$\begin{aligned} & \text{minimize} && \sum_{i=1}^n x_i \pi_i(x_i) \\ & \text{subject to} && \sum_{i=1}^n x_i = X \\ & && 0 < \underline{x}_i \leq x_i \leq \bar{x}_i, \forall i. \end{aligned} \quad (1)$$

By allowing heterogeneity in the price per unit of resource that the aggregator offers to each DER, we can take into account the fact that the aggregator might value classes of DERs differently. For example, the downregulation capacity provided by a residential PV installation (which is achieved by curtailing its power) might be valued differently from the downregulation capacity provided by a TCL or a PHEV (both would need to absorb additional power in order to provide downregulation).

It is not difficult to see that if the price functions $\pi_i(\cdot)$, $i = 1, 2, \dots, n$, are convex

and nondecreasing, then the cost function $\sum_{i=1}^n x_i \pi_i(x_i)$ is convex; thus, if the problem in (1) is feasible, then there exists a globally optimal solution. Additionally, if the price per unit of resource is linear with the amount of resource, i.e., $\pi_i(x_i) = c_i x_i$, $i = 1, 2, \dots, n$, then $x_i \pi_i(x_i) = c_i x_i^2$, $i = 1, 2, \dots, n$, and the problem in (1) reduces to a quadratic program. Also, if the price per unit of resource is constant, i.e., $\pi_i(x_i) = c_i$, $i = 1, 2, \dots, n$, then $x_i \pi_i(x_i) = c_i x_i$, $i = 1, 2, \dots, n$, and the problem in (1) reduces to a linear program. Finally, if $\pi_i(x_i) = \pi(x_i) = c$, $i = 1, 2, \dots, n$, for some constant $c > 0$, i.e., the price offered by the aggregator is constant and the same for all DERs, then the optimization problem in (1) becomes a feasibility problem of the form

$$\begin{aligned} & \text{find} && x_1, x_2, \dots, x_n \\ & \text{subject to} && \sum_{i=1}^n x_i = X \\ & && 0 < \underline{x}_i \leq x_i \leq \bar{x}_i, \forall i. \end{aligned} \quad (2)$$

If the problem in (2) is indeed feasible (i.e., $\sum_{i=1}^n \underline{x}_i \leq X \leq \sum_{i=1}^n \bar{x}_i$), then there is an infinite number of solutions. One such solution, which we refer to as *fair splitting*, is given by

$$x_i = \underline{x}_i + \frac{X - \sum_{l=1}^n \underline{x}_l}{\sum_{l=1}^n (\bar{x}_l - \underline{x}_l)} (\bar{x}_i - \underline{x}_i), \forall i. \quad (3)$$

The formulation to the DER coordination problem provided in (2) is not the only possible one. In this regard, and in the context of PHEVs, several recent works have proposed game-theoretic formulations to the problem (Tushar et al. 2012; Ma et al. 2013; Gharesifard et al. 2013). For example, in Gharesifard et al. (2013), the authors assume that each PHEV is a decision maker and can freely choose to participate after receiving a request from the aggregator. The decision that each PHEV is faced with depends on its own utility function, along with some pricing strategy designed by the aggregator. The

Coordination of Distributed Energy Resources for Provision of Ancillary Services: Architectures and Algorithms, Fig. 1 Control architecture alternatives. (a) Centralized architecture. (b) Decentralized architecture

PHEVs are assumed to be price anticipating in the sense that they are aware of the fact that the pricing is designed by the aggregator with respect to the average energy available. Another alternative is to formulate the DER coordination problem as a scheduling problem (Subramanian et al. 2012; Chen et al. 2012), where the DERs are treated as tasks. Then, the problem is to develop real-time scheduling policies to service these tasks.

Architectures

Next, we describe two possible architectures that can be utilized to implement the proper algorithms for solving the DER coordination problem as formulated in (1). Specifically, we describe a centralized architecture that requires the aggregator to communicate bidirectionally with each DER and a distributed architecture that requires the aggregator to only unidirectionally communicate with a limited number of DERs but requires

some additional exchange of information (not necessarily through bidirectional communication links) among the DERs.

Centralized Architecture

A solution can be achieved through the completely centralized architecture of Fig. 1a, where the aggregator can exchange information with each available DER. In this scenario, each DER can inform the aggregator about its active and/or reactive capacity limits and other operational constraints, e.g., maintenance schedule. After gathering all this information, the aggregator solves the optimization program in (1), the solution of which will determine how to allocate among the resources the total amount of active power P_s^r and/or reactive power Q_s^r that it needs to provide. Then, the aggregator sends individual commands to each DER so they modify their active and or reactive power generation according to the solution of (1) computed by the aggregator. In this centralized solution, however, it is necessary to overlay a communication network

connecting the aggregator with each resource and to maintain knowledge of the resources that are available at any given time.

Decentralized Architecture

An alternative is to use the decentralized control architecture of Fig. 1b, where the aggregator relays information to a limited number of DERs that it can directly communicate with and each DER is able to exchange information with a number of other close-by DERs. For example, the aggregator might broadcast the prices to be paid to each type of DER. Then, through some distributed protocol that adheres to the communication network interconnecting the DERs, the information relayed by the aggregator to this limited number of DERs is disseminated to all other available DERs. This dissemination process may rely on flooding algorithms, message-passing protocols, or linear-iterative algorithms as proposed in Domínguez-García and Hadjicostis (2010, 2011). After the dissemination process is complete and through a distributed computation over the communication network, the DERs can solve the optimization program in (1) and determine its active and/or reactive power contribution.

A decentralized architecture like the one in Fig. 1b may offer several advantages over the centralized one in Fig. 1a, including the following. First, a decentralized architecture may be more economical because it does not require communication between the aggregator and the various DERs. Also, a decentralized architecture does not require the aggregator to have a complete knowledge of the DERs available. Additionally, a decentralized architecture can be more resilient to faults and/or unpredictable behavioral patterns by the DERs. Finally, the practical implementation of such decentralized architecture can rely on inexpensive and simple hardware. For example, the testbed described in Domínguez-García et al. (2012a), which is used to solve a particular instance of the problem in (1), uses Arduino microcontrollers (see Arduino for a description) outfitted with wireless transceivers implementing a ZigBee protocol (see ZigBee for a description).

Algorithms

Ultimately, whether a centralized or a decentralized architecture is adopted, it is necessary to solve the optimization problem in (1). If a centralized architecture is adopted, then solving (1) is relatively straightforward using, e.g., standard gradient-descent algorithms (see, e.g., Bertsekas and Tsitsiklis 1997). Beyond the DER coordination problem and the specific formulation in (1), solving an optimization problem is challenging if a decentralized architecture is adopted (especially if the communication links between DERs are not bidirectional); this has spurred significant research in the last few years (see, e.g., Bertsekas and Tsitsiklis 1997, Xiao et al. 2006, Nedic et al. 2010, Zanella et al. 2011, Gharesifard and Cortes 2012, and the references therein).

In the specific context of the DER coordination problem as formulated in (1), when the cost functions are assumed to be quadratic and the communication between DERs is not bidirectional, an algorithm amenable for implementation in a decentralized architecture like the one in Fig. 1b has been proposed in Domínguez-García et al. (2012a). Also, in the context of Fig. 1b, when the communication between DERs are bidirectional, the DER coordination problem, as formulated in (1), can be solved using an algorithm proposed in Kar and Hug (2012).

As mentioned earlier, when the price offered by the aggregator is constant and identical for all DERs, the problem in (1) reduces to the feasibility problem in (2). One possible solution to this feasibility problem is the fair-splitting solution in (3). Next, we describe a linear-iterative algorithm – originally proposed in Domínguez-García and Hadjicostis (2010, 2011) and referred to as *ratio consensus* – that allows the DERs to individually determine its contribution so that the fair-splitting solution is achieved.

Ratio Consensus: A Distributed Algorithm for Fair Splitting

We assume that each DER is equipped with a processor that can perform simple computations and can exchange information with neighboring

DERs. In particular, the information exchange between DERs can be described by a directed graph $\mathcal{G} = \{\mathcal{V}, \mathcal{E}\}$, where $\mathcal{V} = \{1, 2, \dots, n\}$ is the vertex set (each vertex – or node – corresponds to a DER) and $\mathcal{E} \subseteq \mathcal{V} \times \mathcal{V}$ is the set of edges, where $(i, j) \in \mathcal{E}$ if node i can receive information from node j . We require $\mathcal{G}$ to be *strongly connected*, i.e., for any pair of vertices l and l' , there exists a path that starts in l and ends in l' . Let $\mathcal{L}^+ \subseteq \mathcal{V}$, $\mathcal{L}^+ \neq \emptyset$ denote the set of nodes that the aggregator is able to directly communicate with.

The processor of each DER i maintains two values y_i and z_i , which we refer to as internal states, and updates them (independently of each other) to be, respectively, a linear combination of DER i 's own previous internal states and the previous internal states of all nodes that can possibly transmit information to node i (including itself). In particular, for all $k \geq 0$, each node i updates its two internal states as follows:

$$y_i[k+1] = \sum_{j \in \mathcal{N}_i^-} \frac{1}{\mathcal{D}_j^+} y_j[k], \quad (4)$$

$$z_i[k+1] = \sum_{j \in \mathcal{N}_i^-} \frac{1}{\mathcal{D}_j^+} z_j[k], \quad (5)$$

where $\mathcal{N}_i^- = \{j \in \mathcal{V} : (i, j) \in \mathcal{E}\}$, i.e., all nodes that can possibly transmit information to node i (including itself); and $\mathcal{D}_i^+$ is the out-degree of node i , i.e., the number of nodes to which node i can possibly transmit information (including itself). The initial conditions in (4) are set to $y_i[0] = X/m - \underline{x}_i$ if $i \in \mathcal{L}^+$, and $y_i[0] = -\underline{x}_i$ otherwise and the initial conditions in (5) are set to $z_i[0] = \bar{x}_i - \underline{x}_i$. Then, as shown in Domínguez-García and Hadjicostis (2011), as long as $\sum_{l=1}^n \bar{x}_l \leq X \leq \sum_{l=1}^n \underline{x}_l$, each DER i can asymptotically calculate its contribution as

$$x_i = \underline{x}_i + \gamma(\bar{x}_i - \underline{x}_i) \quad (6)$$

where for all i

$$\lim_{k \rightarrow \infty} \frac{y_i[k]}{z_i[k]} = \frac{X - \sum_{l=1}^n \underline{x}_l}{\sum_{l=1}^n (\bar{x}_l - \underline{x}_l)} := \gamma. \quad (7)$$

It is important to note that the algorithm in (4)–(7) also serves as a primitive for the algorithm proposed in Domínguez-García et al. (2012a), which solves the problem in (1) when the cost function is quadratic. Also, the algorithm in (4)–(7) is not resilient to packet-dropping communication links or imperfect synchronization among the DERs, which makes it difficult to implement in practice; however, there are robustified variants of this algorithm that address these issues Domínguez-García et al. (2012b) and have been demonstrated to work in practice (Domínguez-García et al. 2012a).

Credit Risk Modeling

Tomasz R. Bielecki

Department of Applied Mathematics, Illinois
Institute of Technology, Chicago, IL, USA

Abstract

Modeling of credit risk is concerned with constructing and studying formal models of time evolution of credit ratings (credit migrations) in a pool of credit names, and with studying various properties of such models. In particular, this involves modeling and studying default times and their functionals.

Keywords

Credit risk · Credit migrations · Default time · Markov copulae

Introduction

Modeling of credit risk is concerned with constructing and studying formal models of time evolution of credit ratings (credit migrations) in a pool of N credit names (obligors), and with studying various properties of such models. In particular, this involves modeling and studying default times and their functionals. In many ways, modeling techniques used in credit risk are similar to modeling techniques used in reliability theory. Here, we focus on modeling in continuous time.

Models of credit risk are used for the purpose of valuation and hedging of credit derivatives, for valuation and hedging of counter-party risk, for

assessment of systemic risk in an economy, or for constructing optimal trading strategies involving credit-sensitive financial instruments, among other uses.

Evolution of credit ratings for a single obligor, labeled as i , where $i \in \{1, \dots, N\}$, can be modeled in many possible ways. One popular possibility is to model credit migrations in terms of a jump process, say $C^i = (C_t^i)_{t \geq 0}$, taking values in a finite set, say $\mathcal{K}^i := \{0, 1, 2, \dots, K^i - 1, K^i\}$, representing credit ratings assigned to obligor i . Typically, the rating state K^i represents the state of default of the i -th obligor, and typically it is assumed that process C^i is absorbed at state K^i .

Frequently, the case when $K^i = 1$, that is $\mathcal{K}^i := \{0, 1\}$, is considered. In this case, one is only concerned with jump from the pre-default state 0 to the default state 1, which is usually assumed to be absorbing – the assumption made here as well. It is assumed that process C^i starts from state 0. The (random) time of jump of process C^i from state 0 to state 1 is called the default time, and is denoted as τ^i . Process C^i is now the same as the indicator process of τ^i , which is denoted as H^i and defined as $H_t^i = \mathbb{1}_{\{\tau^i \leq t\}}$, for $t \geq 0$. Consequently, modeling of the process C^i is equivalent to modeling of the default time τ^i .

The ultimate goal of credit risk modeling is to provide a feasible mathematical and computational methodology for modeling the evolution of the multivariate credit migration process $\mathbf{C} := (C^1, \dots, C^N)$, so that relevant functionals of such processes can be computed efficiently. The simplest example of such functional is $P(\mathbf{C}_{t_j} \in A_j, j = 1, 2, \dots, J | \mathcal{G}_s)$, representing the conditional probability, given the information $\mathcal{G}_s$ at time $s \geq 0$, that process $\mathbf{C}$ takes values in the set A_j at time $t_j \geq 0, j = 1, 2, \dots, J$. In particular, in case of modeling of the default times $\tau^i, i = 1, 2, \dots, N$, one is concerned with computing conditional survival probabilities $P(\tau^1 > t_1, \dots, \tau^N > t_N | \mathcal{G}_s)$, which are the same as probabilities $P(H_{t_i}^i = 0, i = 1, 2, \dots, N | \mathcal{G}_s)$.

Based on that, one can compute more complicated functionals, that naturally occur in the context of valuation and hedging of credit risk-sensitive financial instruments, such as corporate

(defaultable) bonds, credit default swaps, credit spread options, collateralized bond obligations, and asset-based securities, for example.

Modeling of Single Default Time Using Conditional Density

Traditionally, there were two main approaches to modeling default times: the structural approach and the reduced approach, also known as the hazard process approach. The main features of both these approaches are presented in Bielecki and Rutkowski (2004).

We focus here on modeling a single default time, denoted as τ , using the so-called conditional density approach of El Karoui et al. (2010). This approach allows for extension of results that can be derived using reduced approach.

The default time τ is a strictly positive random variable defined on the underlying probability space $(\Omega, \mathcal{F}, P)$, which is endowed with a reference filtration, say $\mathbb{F} = (\mathcal{F}_t)_{t \geq 0}$, representing flow of all (relevant) market information available in the model, not including information about occurrence of τ . The information about occurrence of τ is carried by the (right continuous) filtration $\mathbb{H}$ generated by the indicator process $H := (H_t = \mathbb{1}_{\{\tau \leq t\}})_{t \geq 0}$. The full information in the model is represented by filtration $\mathbb{G} := \mathbb{F} \vee \mathbb{H}$.

It is postulated that

$$P(\tau \in d\theta | \mathcal{F}_t) = \alpha_t(\theta) d\theta,$$

for some random field $\alpha(\cdot)$, such that $\alpha_t(\cdot)$ is $\mathcal{F}_t \otimes \mathcal{B}(\mathbb{R}_+)$ measurable for each t . The family $\alpha_t(\cdot)$ is called $\mathcal{F}_t$ -conditional density of τ . In particular, $P(\tau > \theta) = \int_\theta^\infty \alpha_0(u) du$. The following survival processes are associated with τ ,

- $S_t(\theta) := P(\tau > \theta | \mathcal{F}_t) = \int_\theta^\infty \alpha_t(u) du$, which is an $\mathbb{F}$ -martingale,
- $S_t := S_t(t) = P(\tau > t | \mathcal{F}_t)$, which is an $\mathbb{F}$ -supermartingale (Azéma supermartingale).

In particular, $S_0(\theta) = P(\tau > \theta) = \int_\theta^\infty \alpha_0(u) du$, and $S_t(0) = S_0 = 1$.

As an example of computations that can be done using the conditional density approach we give the following result, in which notation “bd” and “ad” stand for before default and at-or-after default, respectively.

Theorem 1 *Let $Y_T(\tau)$ be a $\mathcal{F}_T \vee \sigma(\tau)$ measurable and bounded random variable. Then*

$$E(Y_T(\tau)|\mathcal{F}_t) = Y_t^{\text{bd}} \mathbb{1}_{t < \tau} + Y_t^{\text{ad}}(T, \tau) \mathbb{1}_{t \geq \tau},$$

where

$$Y_t^{\text{bd}} = \frac{\int_t^\infty Y_T(\theta) \alpha_t(\theta) d\theta}{S_t} \mathbb{1}_{S_t > 0},$$

and

$$Y_t^{\text{ad}}(T, \theta) = \frac{E(Y_T(\theta) \alpha_T(\theta) | \mathcal{F}_t)}{\alpha_t(\theta)} \mathbb{1}_{\alpha_t(\theta) > 0}.$$

There is an interesting connection between the conditional density process and the so-called default intensity processes, which are ones of the main objects used in the reduced approach. This connection starts with the following result,

Theorem 2 (i) *The Doob-Meyer (additive) decomposition of the survival process S is given as*

$$S_t = 1 + M_t^{\mathbb{F}} - \int_0^t \alpha_u(u) du,$$

where $M_t^{\mathbb{F}} = -\int_0^t (\alpha_t(u) - \alpha_u(u)) du = E(\int_0^\infty \alpha_u(u) du | \mathcal{F}_t) - 1$.

(ii) *Let $\xi := \inf\{t \geq 0 : S_{t-} = 0\}$. Define $\lambda_t^{\mathbb{F}} = \frac{\alpha_t(t)}{S_t}$ for $t < \xi$ and $\lambda_t^{\mathbb{F}} = \lambda_\xi^{\mathbb{F}}$ for $t \geq \xi$. Then, the multiplicative decomposition of S is given as*

$$S_t = L_t^{\mathbb{F}} e^{-\int_0^t \lambda_u^{\mathbb{F}} du},$$

where

$$dL_t^{\mathbb{F}} = e^{\int_0^t \lambda_u^{\mathbb{F}} du} dM_t^{\mathbb{F}}, \quad L_0^{\mathbb{F}} = 1.$$

The process $\lambda^{\mathbb{F}}$ is called the $\mathbb{F}$ intensity of τ .

The $\mathbb{G}$ -compensator of τ is the $\mathbb{G}$ -predictable increasing process $\Lambda^{\mathbb{G}}$ such that the process

$$M_t^{\mathbb{G}} = H_t - \Lambda_t^{\mathbb{G}}$$

is a $\mathbb{G}$ -martingale. If $\Lambda^{\mathbb{G}}$ is absolutely continuous, the $\mathbb{G}$ -adapted process $\lambda^{\mathbb{G}}$ such that

$$\Lambda_t^{\mathbb{G}} = \int_0^t \lambda_u^{\mathbb{G}} du$$

is called the $\mathbb{G}$ -intensity of τ . The $\mathbb{G}$ -compensator is stopped at τ , i.e., $\Lambda_t^{\mathbb{G}} = \Lambda_{t \wedge \tau}^{\mathbb{G}}$. Hence, $\lambda_t^{\mathbb{G}} = 0$ when $t > \tau$. In particular, we have

$$\lambda_t^{\mathbb{G}} = \mathbb{1}_{t < \tau} \lambda_t^{\mathbb{F}} = (1 - H_t) \lambda_t^{\mathbb{F}}.$$

The conditional density process and the $\mathbb{G}$ -intensity of τ are related as follows: For any $t < \xi$ and $\theta \geq t$ we have

$$\alpha_t(\theta) = E(\lambda_\theta^{\mathbb{G}} | \mathcal{F}_t).$$

Example 1 This is a structural-model-like example

- Suppose $\mathbb{F} = \mathbb{F}^X$ is a filtration of a default driver process, say X , and Θ is the default barrier assumed to be independent of X . Denote $G(t) = P(\Theta > t)$.
- Define

$$\tau := \inf\{t \geq 0 : \Gamma_t \geq \Theta\},$$

with $\Gamma_t := \sup_{s \leq t} X_s$. We then have $S_t(\theta) = G(\Gamma_\theta)$ if $\theta \leq t$ and $S_t(\theta) = E(G(\Gamma_\theta) | \mathcal{F}_t^X)$ if $\theta > t$

- Assume that $F = 1 - G$ and Γ are absolutely continuous w.r.t. Lebesgue measure, with respective densities f and γ . We then have

$$\alpha_t(\theta) = f(\Gamma_\theta) \gamma_\theta = \alpha_\theta, \quad t \geq \theta,$$

and $\mathbb{F}^X$ intensity of τ is

$$\lambda_t = \frac{\alpha_t(t)}{G(\Gamma_t)} = \frac{\alpha_t(t)}{S_t}.$$

- In particular, if Θ is a unit exponential r.v., that is, if $G(t) = e^{-t}$ for $t \geq 0$, then we have that $\lambda_t = \gamma_t = \frac{\alpha_t(t)}{S_t}$.

Example 2 This is a reduced-form-like example.

- Suppose S is a strictly positive process. Then, the $\mathbb{F}$ -hazard process of τ is denoted by $\Gamma^\mathbb{F}$ and is given as

$$\Gamma_t^\mathbb{F} = -\ln S_t, \quad t \geq 0.$$

In other words,

$$S_t = e^{-\Gamma_t^\mathbb{F}}, \quad t \geq 0.$$

- In particular, if $\Gamma^\mathbb{F}$ is absolutely continuous, that is, $\Gamma_t^\mathbb{F} = \int_0^t \gamma_u^\mathbb{F} du$ then

$$S_t = e^{-\int_0^t \gamma_u^\mathbb{F} du}, \quad t \geq 0 \quad \text{and}$$

$$\alpha_t(\theta) = \gamma_\theta^\mathbb{F} S_\theta, \quad t \geq \theta.$$

Modeling Evolution of Credit Ratings Using Markov Copulae

The key goal in modeling of the joint migration process $\mathbf{C}$ is that the distributional laws of the individual migration components C^i , $i \in \{1, \dots, N\}$, agree with given (predetermined) laws. The reason for this is that the marginal laws of $\mathbf{C}$, that is, the laws of C^i , $i \in \{1, \dots, N\}$, can be calibrated from market quotes for prices of individual (as opposed to basket) credit derivatives, such as the credit default swaps, and thus, the marginals of $\mathbf{C}$ should have laws agreeing with the market data.

One way of achieving this goal is to model $\mathbf{C}$ as a Markov chain satisfying the so-called Markov copula property. For brevity we present here the simplest such model, in which the reference filtration $\mathbb{F}$ is trivial, assuming additionally, but without loss of generality, that $N = 2$ and that $\mathcal{K}^1 = \mathcal{K}^2 = \mathcal{K} := \{0, 1, \dots, K\}$.

Here we focus on the case of the so-called strong Markov copula property, which is reflected in Theorem 3.

Let us consider two Markov chains Z^1 and Z^2 on $(\Omega, \mathcal{F}, P)$, taking values in a finite state space $\mathcal{K}$, and with the infinitesimal generators $A^1 := [a_{ij}^1]$ and $A^2 := [a_{hk}^2]$, respectively.

Consider the system of linear algebraic equations in unknowns $a_{ih,jk}^{\mathbf{C}}$,

$$\sum_{k \in \mathcal{K}} a_{ih,jk}^{\mathbf{C}} = a_{ij}^1, \quad \forall i, j, h \in \mathcal{K}, \quad i \neq j, \quad (1)$$

$$\sum_{j \in \mathcal{K}} a_{ih,jk}^{\mathbf{C}} = a_{hk}^2, \quad \forall i, h, k \in \mathcal{K}, \quad h \neq k, \quad (2)$$

It can be shown that this system admits at least one positive solution.

Theorem 3 Consider an arbitrary positive solution of the system (1) and (2). Then the matrix $A^{\mathbf{C}} = [a_{ih,jk}^{\mathbf{C}}]_{i,h,j,k \in \mathcal{K}}$ (where diagonal elements are defined appropriately) satisfies the conditions for a generator matrix of a bivariate time-homogeneous Markov chain, say $\mathbf{C} = (C^1, C^2)$, whose components are Markov chains in the filtration of $\mathbf{C}$ and with the same laws as Z^1 and Z^2 .

Consequently, the system (1) and (2) serves as a Markov copula between the Markovian margins C^1, C^2 and the bivariate Markov chain $\mathbf{C}$.

Note that the system (1) and (2) can contain more unknowns than the number of equations, therefore being underdetermined, which is a crucial feature for ability of calibration of the joint migration process $\mathbf{C}$ to marginal market data.

Example 3 This example illustrates modeling joint defaults using strong Markov copula theory.

Let us consider two processes, Z^1 and Z^2 , that are time-homogeneous Markov chains, each taking values in the state space $\{0, 1\}$, with respective generators

$$A^1 = \begin{matrix} & \begin{matrix} 0 & 1 \end{matrix} \\ \begin{matrix} 0 \\ 1 \end{matrix} & \begin{pmatrix} -(a+c) & a+c \\ 0 & 0 \end{pmatrix} \end{matrix} \quad (3)$$

and

$$A^2 = \begin{matrix} & \begin{matrix} 0 & 1 \end{matrix} \\ \begin{matrix} 0 \\ 1 \end{matrix} & \begin{pmatrix} -(b+c) & b+c \\ 0 & 0 \end{pmatrix} \end{matrix}, \quad (4)$$

for $a, b, c \geq 0$.

The off-diagonal elements of the matrix $A^{\mathbf{C}}$ below satisfy the system (1) and (2),

$$A^C = \begin{matrix} & \begin{matrix} (0, 0) & (0, 1) & (1, 0) & (1, 1) \end{matrix} \\ \begin{matrix} (0, 0) \\ (0, 1) \\ (1, 0) \\ (1, 1) \end{matrix} & \begin{pmatrix} -(a + b + c) & b & a & c \\ 0 & -(a + c) & 0 & a + c \\ 0 & 0 & -(b + c) & b + c \\ 0 & 0 & 0 & 0 \end{pmatrix} \end{matrix} \tag{5}$$

C

Thus, matrix A^C generates a Markovian joint migration process $C = (C^1, C^2)$, whose components C^1 and C^2 model individual default with prescribed default intensities $a + c$ and $b + c$, respectively.

For more information about Markov copulae and about their applications in credit risk we, refer to Bielecki et al. (2013).

Subaquática (LSTS), Faculdade de Engenharia
da Universidade do Porto, Porto, Portugal

Abstract

Recent and exciting developments in robotic systems for maritime operations are presented along with projections of future applications. This will provide the background against which we will discuss new research challenges, lying at the intersection of control and computation. First, current practices and trends in robotic systems are reviewed. Second, future maritime operations are discussed with reference to a paradigm shift: from robotic systems to systems of robotic systems. Finally, the control and computation challenges posed by future robotic operations are discussed in the framework of cyber-

physical systems in which physical and computational entities co-evolve, interact, and communicate in an environment that can also be modified by the actions of these entities. This will be done with reference to modular design, systems of systems, models of systems with evolving structure, optimization and execution control for extended space-control spaces, and hierarchical control architectures.

Keywords

Autonomous underwater vehicles · Autonomous surface vehicles · Unmanned air systems · Ocean exploration · Networked vehicle systems · Robotic teams · Control hierarchies

Introduction

It took only a few decades for robotic underwater, surface, and air vehicles to revolutionize maritime operations (Bellingham and Rajan 2007; Curtin et al. 1993; Yang et al. 2018). This was driven by an application pull from science, industry, and the military, as well as by advances in computation, communication, energy storage, materials, and sensing technologies. But this is just the beginning.

Future maritime operations will involve large numbers of heterogeneous robots with significant functional diversity and endurance. Meanwhile, as robotic vehicles reach new levels of reliability and operability, operations are expected to move to remote and communications-challenged environments. Heterogeneity and functional diversity will enable new group capabilities and new concepts of operation. Robots will be organized into teams delivering capabilities that cannot be provided by isolated robots. Teams will be dynamically created, disbanded, and allocated to tasks and will cooperate with other teams, as well as with manned assets. But this will require a paradigm shift: from robotic systems to systems of robotic systems.

Here we discuss the state of the art, the current practice, trends, and operations before turning into future challenges in cyber-physical maritime robotic systems.

Background in Maritime Robotic Vehicles

Maritime robots come in several shapes, sizes, and categories. Autonomous underwater vehicles (AUVs) are unmanned and untethered submersibles. Autonomous surface vehicles (ASVs) and unmanned air vehicles (UAV) are, respectively, their surface and aerial counterparts (Fig. 1). Remotely operated vehicles (ROVs) are tethered submersibles remotely controlled by a human pilot. Finally, autonomous ships are a class on their own, mainly because of specific regulatory frameworks.

However, and despite the terminology, most of the commercially available maritime robots are not autonomous because they lack onboard decision-making capabilities. In fact, these are automated vehicles because “sensing and acting” are mediated by scripted control procedures.

Technological trends, capabilities, and future operations are better understood in terms of the product hierarchy of a maritime robot, typically comprising several subsystems: mechanical, propulsion, energy, communications, navigation, computers, payload, auxiliary equipment, and vehicle application and system software. We briefly discuss these subsystems from the cyber-physical systems viewpoint.

Energy storage and management still represent one of the main design constraints for maritime robotic systems. Cost and energy density will be positively impacted by advances in battery technology. Fuel cell technology is a potential game-changer, but there are still a few obstacles to operational deployments, especially for small vehicles. Mechanisms for harvesting energy from waves, wind, and the sun have been successfully deployed in ocean vehicles. Mechanisms for energy transfer from docking stations are under

Cyber-Physical Maritime Robotic Systems, Fig. 1 Autonomous air, underwater, and surface vehicles (from left to right: vertical take-off and landing UAV, light

autonomous underwater vehicle, Autonaut ASV (<https://www.autonautusv.com/>))

C

development and have already been deployed at sea to support, for example, resident AUVs. Energy management systems are also evolving to optimize energy consumption and power generation.

The aerodynamic and hydrodynamic performance of robotic vehicles has been improving due to advances in composite materials and mechanical design. The highly nonlinear dependence of drag on the velocity of a vehicle tends to favor the design of slow-moving vehicles, especially if mission duration is the key design parameter. For example, AUVs with buoyancy engines and active control of the center of mass, also called gliders, are now the mainstay for long-endurance data collection at sea.

Underwater and above water communications pose significant challenges to operations. Above water communications typically rely on radio technology. Future space-based Internet communications are expected to revolutionize communications at sea, mainly in remote locations. Underwater communications have relied mostly on slow acoustic communications (ranges of up to a few Km and data rates of up to a few kilobytes per second) despite recent advances in short-range optical communications (ranges of up to tens of meters and data rates in the order of hundreds of kilobytes per second). All these limitations pose significant challenges to the deployment of inter-operated communication networks (Zolich et al. 2019). This is also why delay- and disruptive-tolerant networking protocols (<https://www.nasa.gov/content/dtn>) are already enabling vehicles to transparently ferry data packets between communication nodes that are not connected.

Navigation and positioning are yet another main challenge in maritime robotics, especially for underwater vehicles. This is mainly because GPS is not available underwater. High-precision underwater navigation still relies on expensive inertial measurement units and current profilers (to measure velocity relative to the water column or the bottom of the ocean) typically aided by feature-based navigation algorithms or acoustic localization systems (that measure distances to acoustic beacons). Acoustic technologies are also a low-cost, yet range-constrained, approach to underwater localization. The combination of external navigation aids and high-precision navigation sensors is required for high-precision underwater mapping. This is not the case with ocean gliders, which typically use low-cost navigation solutions, initialized with the last GPS fix.

Current Practices and Trends

The motions of maritime robots are typically described by nonlinear models in 6 degrees of freedom (Fossen 2002). These models have a significant number of parameters to describe how forces and moments affect the motions of the robot. However, the estimation of some of these parameters is typically very expensive, thus making it prohibitive for low-cost vehicles. This also poses additional control challenges because of model uncertainty. Also, most of the ocean-going vehicles are underactuated (to reduce cost or maximize hydrodynamic performance), and control surfaces (used for steering in some vehicles) are not effective at low speeds. Moreover, state

estimation is quite difficult, not only because of nonlinear behavior and model approximations but also because accelerations and velocities are hard to measure, except with high-end navigation sensors. This is the background against which we briefly discuss selected current navigation and control practices and trends.

Acoustic navigation techniques have evolved from measuring roundtrip time of flight to multiple beacons (Whitcomb et al. 1998) to the measurement of one-way travel time, done with the help of high-precision synchronized clocks used by each beacon to send acoustic pings on a tight schedule (Eustice et al. 2011). This technique is scalable with the number of beacons and serves multiple vehicles. Another advance came with the advent of single-beacon navigation techniques and associated observability results (Batista et al. 2010). Cooperative navigation techniques improved the navigation performance of multiple vehicles by combining acoustic localization techniques and communications (Webster et al. 2013). Other developments in navigation have focused on the deterministic estimators (Bryne et al. 2017; Kinsey and Whitcomb 2007) designed with the help of Lyapunov-based stability theory, thus departing from stochastic estimators, such as the extended Kalman filter and the unscented Kalman filter (Julier and Uhlmann 2004), based on approximate minimum variance filtering.

Several variations of problems of path following and trajectory tracking for underactuated vehicles have been addressed over the years (Aguiar and Hespanha 2007; Paliotta et al. 2019). Cooperative control problems, typically expressed in terms of formation control constraints for multiple vehicles, have been formulated and solved in the framework of nonlinear control techniques (Fiorelli et al. 2006; Alessandretti and Aguiar 2020). Variations of these problems involve acoustic communication exchanges that are typically affected by time-varying delays, low data rates, and dropouts (Abreu et al. 2015; Hung and Pascoal 2018).

Multiple underwater and surface vehicles have already performed cooperative missions in world oceans (Fiorelli et al. 2006; Sato et al. 2019;

Ferreira et al. 2019; Hobson et al. 2018). These have been enabled by advances in autonomy, namely, in what regards autonomous feature tracking (Zhang and Chen 2018; Branch et al. 2019) and in statistical methods (Fossum et al. 2019). Meanwhile, several science cruises have demonstrated new methods and technologies for ocean observation. Examples include the use of ship-based unmanned air vehicles to study air-sea fluxes (Zappa et al. 2020) and the demonstration of a novel approach to study an ocean front based on the coordinated ship-robotic surveys involving autonomous underwater, surface, and air vehicles (Belkin et al. 2018).

Future Applications

The pull from future applications comes primarily from science, offshore industry, ship automation, security, and the military, as briefly discussed next.

Our oceans are in trouble. The United Nations has proclaimed a Decade of Ocean Science for Sustainable Development (2021–2030) to support efforts to reverse the cycle of decline in ocean health (<https://en.unesco.org/ocean-decade>). But this calls for a comprehensive evaluation of the health of the oceans and the development of informed ocean sustainability and sustenance policies. The problem is that the oceans are under-sampled, mainly because the traditional ship and remote-sensing methods are not cost-effective and do not provide the required spatial and temporal resolutions. This aim can only be achieved with the help of coordinated observations from space, aerial, surface, and underwater robots guided by artificial intelligence for adaptive spatial and temporal resolutions.

The offshore industry, as well as ports and coastal management, has already relied on autonomous underwater, surface, and air vehicles for routine operations. As offshore operations move to deeper waters, and complex machinery is deployed at the bottom of the ocean, the demand for new underwater inspection, monitoring, and intervention vehicles is increasing. Meanwhile,

future offshore platforms are expected to have high degrees of automation and to support interactions with robotic vehicles. For example, docking stations, delivering energy and communications, will support the operation of resident vehicles, and through-water wireless optical modems, delivering broadband communications, will enable, for example, closed-loop visual inspection with humans in the loop. In yet another concept, underwater vehicles will be autonomously launched and recovered from surface vehicles to minimize cost and expand the operational envelope.

Currently, the shipping industry is actively working on autonomous ships, with a special focus on high levels of automation and reliability. The trend is also towards systems of systems encompassing ship and harbor automation. In some future concepts, multiple robots, including autonomous ships, will support cargo transfer and other types of operations.

The military and security applications will also emphasize combined operations with large numbers of specialized assets and supporting the operation of manned assets.

Future Maritime Robotic Operations

The pull from applications and the accelerating pace of technological change will significantly shape the future landscape of maritime operations.

The number and diversity of manned and unmanned assets involved in maritime operations will increase significantly with respect to what is done today. One trend is towards systems of systems in which robotic and manned assets with complementary sensing, actuation, computation, communication, transportation, and refueling capabilities will form multi-functional teams delivering system-level capabilities that are a function of the assets, of communications networks, and of the interactions established among these assets. This will be enabled by the exchange of data and commands over interoperated underwater and above water communication networks, with support for disruptive- and

delay-tolerant networking protocols. Another significant trend is towards increased autonomy for robotic systems, as well as for systems of systems, with provisions for mixed-initiative interactions, to allow intervention in planning and control loops by experienced human operators. Yet, new opportunities also lie ahead for all-weather persistent operations in remote and communications-challenged environments (e.g., bottom of the ocean or the Arctic) (Fig. 2).

Future Directions

Here we discuss future directions, starting with robotic vehicles, as components of larger systems, before elaborating on what lies ahead for systems of robotic systems.

Robotic Vehicles

Some of the key navigation and control challenges will come from all-weather operations, autonomous launch and recovery, docking operations, interactions with infrastructures, *cloud*-based operations (Adaldo et al. 2017), and mapping and tracking of natural or man-made features.

Planning for long-endurance operations will require high-resolution ocean/weather models to minimize exposure to adverse environmental conditions or to maximize the energy harvested from waves, wind, or the sun (Aguilar et al. 2018; Lermusiaux et al. 2016). This will require a tradeoff between the need to minimize communication exchanges and the need to use cloud-based high-resolution models. A related challenge will come from active power management to balance motion, communication, and energy harvesting requirements.

Autonomous launch and recovery of robotic vehicles from unmanned or manned assets will present new relative positioning and control challenges, especially in what regards robustness and safety guarantees. These problems will become even more challenging in inspection and intervention operations because of uncontrolled interactions due to proximity to other infrastructures. Proximity will enable fast short-range light-based

Cyber-Physical Maritime Robotic Systems,

Fig. 2 Preview of future maritime robotic systems

communications to complement slower longer-range acoustic-based communications.

Cloud-based systems will support operations in remote and communications-challenged environments enabling interactions with remote vehicles (e.g., commands will be available at some cloud service for future retrieval by an autonomous underwater vehicle when it surfaces). Yet another future direction concerns the development of feature mapping and tracking capabilities (e.g., of isolines for temperature or salinity), driven by sensor readings, to study dynamic features of the ocean with adaptive spatial and temporal resolutions.

Fault identification and recovery techniques, as well as onboard risk management, will become increasingly sophisticated for robots to achieve the levels of operational reliability and safety guarantees required for operation in the world's oceans. This is especially important for autonomous ships.

Finally, robotic vehicles should be enabled for interactions to support integration into systems of systems. This poses interoperability challenges, not only for communications, command, and control but also for launch and recovery and docking mechanisms. Other key enablers for interactions are control primitives for spatial-temporal rendezvous, docking, motions in restricted spaces, path and trajectory following,

tracking of environmental features, target tracking, and formation control.

Cyber-physical Systems of Robotic Systems

The true nature of future maritime cyber-physical systems is better understood from the perspective of systems of systems. These will be cyber-physical systems in which physical entities, such as robots or control stations, and computational entities, such as computer programs, will evolve and interact enabled by mobile computation. Mobile computation, in turn, entails virtual mobility (mobile software) and physical mobility (mobile hardware), also called mobile computing (Cardelli and Gordon 1998). Physical entities are governed by the laws of physics, computational entities by the laws of computation. Physical entities evolve in the physical environment, may interact among themselves and with the environment, and can be “composed” to form other physical entities. Computational entities evolve in the computational environment formed by communicating physical entities, interact through communications, may be created and deleted on the fly, can be composed with other computational entities, and may also migrate between communicating physical entities. The mappings from computational entities to the physical entities in which they reside may change

with time, thus providing new mechanisms for reconfiguration and resilience to failures.

Models of Systems with Evolving Structure

Currently, we still lack formal modeling frameworks to support the analysis and synthesis of cyber-physical systems of systems. This is in part because research in control engineering has not yet incorporated concepts such as link, interaction, and dynamic structure, let alone concepts of mobile connectivity and mobile locality. Researchers in computer science were already developing these concepts in the early 1990s (Milner 96). The problem of mobile connectivity was addressed in the Pi-calculus (Milner 99), a calculus of communicating systems in which the components of a system may be arbitrarily linked, and communications over linked neighbors may carry information which changes that linkage. The problem of mobile locality was addressed almost one decade later, in part because of the advent of ubiquitous mobile computing, by the theory of Bi-graphical Reactive Systems (BRS's) (Milner 2009). The theory is based on the bi-graph model of mobile computation, with both mobile locality and connectivity. A bi-graph has a place graph, representing locations of computational nodes in a tree structure; a link graph, representing the interconnection of these nodes; and a set of reaction rules describing the connectivity and locality dynamics. However, BRS has several modeling limitations. This is because the reaction rules do not encompass the continuous-time mobility of physical entities and do not provide constructs for mobile locality and connectivity matching the dynamics of physical and computational entities. These limitations are not present in a model of dynamic networks of hybrid automata (DNHA) describing systems consisting of automata components that can be created, interconnected, and destroyed as the system evolves. In this model, there are two types of interactions for a hybrid automaton: (i) differential inclusions, guards, jump, and reset relations that are functions of variables from other automata and (ii) exchange of events among automata. The SHIFT language (Desh-

pande et al. 1998) implemented DNHA with formal syntax and semantics that incorporates first-order predicate logic used to dynamically reconfigure input/output connections and synchronous composition. However, synchronous composition lacks expressivity to model communications in general robotic networks, and the dynamic configuration mechanisms are just too complex for formal analysis and verification. Further research is needed into models having physical and computational entities as atomic entities, as well as coupled physical and computational dynamics.

Optimization and Execution Control in Extended Space-Control Spaces

Physical robots are abstracted by coupled energy, computation, motion, sensing, communication, and actuation capabilities. Computational entities present additional coupling constraints. Accordingly, optimization and control problems for maritime cyber-physical systems will have to be formulated in extended hybrid state-control spaces with continuous-time components, as well as discrete components, including set-valued variables (e.g., to model time-varying interactions). The concept of reach sets for these state spaces will allow the generalization of other control engineering concepts, such as invariance and optimization. In fact, several behavioral specifications can be translated into new invariance, reachability, or optimization problems in these hybrid extended state-control spaces. Conceptually, these problems can be solved in the framework of dynamic optimization, which has been extensively applied to solving optimal hybrid control problems (Branicky and Mitter 1995; Sethian and Vladimirovsky 2002).

Recent advances in the implementation of numerical methods to solve the Hamilton-Jacobi-Bellman variational inequalities (Branicky and Mitter 1995) resulting from the application of the dynamic programming principle motivated the development of modular solutions to problems in multi-vehicle planning and execution control (Aguilar et al. 2020). Further developments are also needed in this area.

Organizational Concepts

The nature of future robotic systems will go beyond analogies to human organizations. This is because physical and computational entities will evolve and interact in ways that have no parallel in human endeavors. The relevance of organizational concepts has already been demonstrated in automated highway systems – AHS (Horowitz and Varaiya 2000), mobile offshore bases (Borges de Sousa et al. 2000), mixed-initiative control of automata teams (Borges de Sousa et al. 2004), and coordinated robotics for ocean operations (Ferreira et al. 2019; Fossum et al. 2019; Belkin et al. 2018), all of which shared hierarchical organization principles (Varaiya 2000) drawing inspiration from the layered structure of software systems (e.g., the Internet protocol stack).

The AHS was a distributed and hierarchical control system that aimed to increase highway capacity, safety, and efficiency without building more roads. In this concept, a highway system is organized into a network in which sections, with limited flow capacities, connect one or more junctions, and traffic is organized into groups of tightly spaced vehicles, called platoons. The size of the platoons depends on the flow capacity of each section. The salient feature of the AHS architecture is that it breaks down AHS control into five self-contained hierarchically organized functional layers, thus providing us with a semantic framework in which we extract sub-problems from AHS and reason about them in self-contained theories.

New organization concepts involving teams, sub-teams, tasks, and subtasks were adopted in the hierarchical control of unmanned air vehicle teams for military operations (Borges de Sousa et al. 2004). Problems of task decomposition, task allocation to teams, team coordination, dynamic re-tasking, and reallocation were solved within a dynamic hierarchy of interacting team, sub-team, and maneuver controllers. Coordination among controllers was based on a few coordination variables describing the state of execution for each controller (e.g., for load balancing strategies among teams). Teams were also directly addressed by name to enable team-level command and control primitives. The structure

of controllers and the dynamics of interactions within this structure enabled this system of systems to have some degree of resiliency to the elimination of UAVs.

Further research is needed to study the relations between system-level properties, such as resilience and agility, and dynamic structure. This research would benefit from the study of the emergence of these properties in nature. For man-made systems, this would require the development of mechanisms to dynamically map teams to capabilities, to develop team controllers to deliver team capabilities, even in the presence of disturbances, and possibly through dynamic allocation of controllers to vehicles. This will require formal compositional frameworks with performance guarantees. However, the composition can only be achieved if systems are designed for interaction.

Connections between models of systems with evolving structure and control hierarchies were established in the development of a verified hierarchical control architecture for a robotic team (Borges de Sousa et al. 2007). By design, the architecture satisfies a formal specification for the behavior of the team in the sense of a bi-simulation relation between two hybrid automata, one encoding the control architecture and the other the specification.

Further investigations are needed to study behavioral equivalence for systems with evolving structure and coupled physical and computational dynamics. In this setting, the control design problem consists of deriving a structure of computational entities that, when “composed” with the system, satisfies a formal specification in some sense of behavioral equivalence.

Finally, further research in distributed artificial intelligence is required to achieve high levels of deliberation (Py et al. 2016; McGann et al. 2008) in the framework of systems with dynamic structure and functional composition.

Abstract

Recent cyberattacks targeting critical infrastructures, such as power systems and nuclear facilities, have shown that malicious, advanced attacks on control and monitoring systems are a serious concern. These systems rely on tight integration of cyber and physical

components, implying that cyberattacks may have serious physical consequences. This has led to an increased interest for Cyber-Physical Systems (CPS) security, and we here review some of the fundamental problems considered. We review basic modeling of the CPS components in networked control systems and how to model a cyberattack. We discuss different classes of attack strategies and the resources required. Particular attention is given to analysis of detectability and impact of attacks. For the system operator, attack mitigation is a particular concern, and we review some common strategies. Finally, we point out future directions for research.

Keywords

Attack mitigation · Attack modeling · CPS · Denial-of-service attack · Detectability · Eavesdropping attack · Impact · Replay attack · Stealth attack · Undetectable attack

Introduction

Control systems are essential elements in many critical infrastructures and govern the interaction of the cyber and physical components. A modern control system contains application programs running on a host computer or embedded devices and constitutes an important instance of CPS. Historically, cybersecurity has not been a concern for these systems. However, recent incidents have clearly illustrated that malicious corruption of signals in control and monitoring systems is a legitimate, serious attack vector. Several malwares dedicated to attacking control and monitoring systems in nuclear facilities and power systems, for example, have been discovered (Hemsley and Fisher 2018). Security has therefore in the last decade become an important topic on the research agenda of control system designers (Cardenas 2019). Unlike traditional security research, the development of security-enhancing mechanisms that leverage the control system itself is key. These mechanisms do not eliminate the need for traditional security

technologies, such as encryption or authentication, but should rather be seen as complements that are able to mitigate attack vectors that are hard, or even impossible, to detect on the lower protocol layers.

Three fundamental properties of information and services in IT systems are analyzed in the cybersecurity literature (Bishop 2002) using the acronym CIA: *confidentiality* (C), *integrity* (I), and *availability* (A). Confidentiality concerns the concealment of data, ensuring it remains known to the authorized parties alone. Integrity relates to the trustworthiness of data, meaning there is no unauthorized change to the information between the source and destination. Availability considers the timely access to information or system functionalities. These properties are relevant in CPS security as well, and our review will use them for classification of attack strategies.

Networked Control System Under Attack

CPS Components and Signals

In Fig. 1, a block diagram of a networked control system is shown. Networked control systems are special instances of CPS, containing strongly interacting components in both the cyber and physical domains. The signals $\tilde{u}$ (input to plant P) and y (output from plant P) can be thought of as physical quantities, where the physical effects of CPS attacks will be realized and sensed. These signals are sampled and communicated over a computer network, possibly under (partial) control of a malicious attacker; see section “CPS Attack Space.” The sampled signals u and $\tilde{y}$ are outputs and inputs to the feedback controller C . Note that in the presence of an attacker in the network, the signals may be different from their plant-side counterparts $\tilde{u}$ and y . It is commonly assumed that an anomaly detector D is co-allocated with the controller, although the detector may run on a different platform. The role of the detector is to generate alarms to alert the operator of unusual system behavior, caused by faults or attacks, for instance. Often the detectors are model-based fault-detection-type filters (see

Blanke et al. 2015, for instance), which sometimes can detect also malicious cyberattacks.

CPS Attack Space

In CPS security, it is commonly assumed cyberattacks are carried out through the network, as illustrated in Fig. 1, with the overall intention of disrupting the CPS. The attacker has three general modes of operation: By listening to the network traffic ($c_u = u$ and/or $c_y = y$), the attacker violates the confidentiality (property **C**) of the system. By modifying the content of the network traffic ($i_u \neq 0$ and/or $i_y \neq 0$), the attacker violates the integrity (property **I**) of the system. Finally, by dropping communication packets ($a_u = \text{OPEN}$ and/or $a_y = \text{OPEN}$), the attacker violates the availability (property **A**) of the system. Other modes of cyberattack, for instance, assuming that the attacker is able to modify controller or sensor software directly, may also be of interest. From a practical IT perspective, such attacks may be very different from the network-based attacks illustrated in Fig. 1. On the other hand, from a high-level control, physical impact, and detectability perspective, one can often model also such attacks by an appropriate choice of the signals $c_u, c_y, i_u, i_y, a_u, a_y$.

To compare different attack strategies, a CPS attack space was used in Teixeira et al. (2015), see Fig. 2. The three axes quantify the level of resources the attacker possesses.

Disclosure resources measure how many network communication signals the attacker can listen to. That is, an attacker that can read all elements of signals y and u is more powerful than an attacker with only occasional access to some elements. *Disruption resources* measure the number of network signals the attacker can alter through integrity or availability attacks. Finally, *CPS model knowledge* quantifies the accuracy of the models of system components the attacker has access to. Some commonly considered attack strategies are mapped in Fig. 2 and are discussed in more detail next.

Eavesdropping attacks (see Leong et al. 2018, for instance) involve an attacker who is not actively altering data, but rather listens and records network traffic ($c_u = u$ and/or $c_y = y$). Such attacks are of high importance in privacy-sensitive applications, but could also be a precursor to physically damaging attacks. The attacker could carry out system identification or machine learning on recorded data (u, y) to obtain the CPS model knowledge required for other attack strategies.

Replay attacks (see Mo and Sinopoli 2009, for instance) start with the recording of data, similar to an eavesdropping attack. In the second stage of the attack, the attacker replays captured outputs ($a_y = \text{OPEN}$ and $i_y = y_{\text{old}}$) while he is applying harmful control commands on the plant ($i_u \neq 0$).

Cyber-Physical Security,

Fig. 1 Block diagram of networked control system. Through the network communication system, the attacker may be able to intercept and corrupt the communication between the controller (C) and the physical plant (P). It is common in the CPS security area to assume that the operator has an anomaly detector (D) installed

Cyber-Physical Security, Fig. 2 The CPS attack space (Teixeira et al. 2015) maps out different attack strategies along three axes, each measuring the relative amount of attack resources required

Stealthy data-injection attacks (see Teixeira et al. 2015, for instance) involve an attacker with significant CPS model knowledge. The attacker exploits this knowledge to create integrity attacks ($i_u \neq 0$ and/or $i_y \neq 0$) so that the disrupted signals ($\tilde{u}, \tilde{y}$) appear similar to regular signals and do not trigger alarms in the anomaly detector. Note that the attacker here does not simply repeat old captured signals but actually generates new carefully crafted signals that may be more challenging to deem anomalous.

Denial-of-service (DoS) attacks (see Amin et al. 2009, for instance) involve an attacker that disrupts the communication between the controller and the plant ($a_u = \text{OPEN}$ and/or $a_y = \text{OPEN}$) by dropping packets in the communication network. There are often natural losses of packets in communication networks depending on the implementation, and so the detectability and physical impact depend on the exact attack strategy.

Properties of Attack Strategies

To determine the cyberattack vulnerability of a networked control system, it is important to understand the possibility for a CPS operator to *detect* an ongoing cyberattack, as well as the attack's possible physical *impact*.

Detectability

Undetectable attacks (see Pasqualetti et al. 2013, for instance) are attacks whose impact on the detector signals ($u, \tilde{y}$) are such that they could have resulted from an unknown initial state in the plant P (without the attacker present). An integrity attack signal (i_u, i_y) is undetectable if the measurement satisfies

$$\tilde{y}_t(x_0, i_u, i_y) = \tilde{y}_t(\bar{x}_0, 0, 0), \quad (1)$$

for all times t and some possibly different plant initial states $x_0, \bar{x}_0$. These attacks may be very hard, or even impossible, for the detector to catch since the measurement exactly corresponds to unperturbed physical behavior of the plant. The possibility of undetectable attacks is equivalent to the closed-loop system having non-trivial zero dynamics, and sometimes these attacks are referred to as *zero-dynamics attacks*. If the plant is linear, dangerous destabilizing undetectable attacks exist when the plant has unstable invariant zeros (by injecting exponentially growing i_u) or unstable poles (by injecting exponentially growing i_y).

A statistically based anomaly detector could check if the received signals ($u, \tilde{y}$) are likely or not, and not only if they exactly correspond to possible unperturbed plant behavior (1). Such a detector could raise an alarm also when “unde-

teable” attacks are staged. An attacker who would like to remain hidden may thus want to include a model of the anomaly detector during the attack design.

Stealth attacks (see Teixeira et al. 2015, for instance) are attacks that are designed such that a particular detector does not trigger an alarm. The attacker needs to have a model of the detector and its thresholds to design these attacks. For detectors that only check whether the signals $(u, \tilde{y})$ satisfy the unperturbed plant dynamics, undetectable attacks constitute examples of stealth attacks. But generally it is possible for stealth attacks to deviate from the plant dynamics quite a bit without generating alarms, since otherwise the detectors would generate too many false alarms in practice.

For linear stochastic plants with realization (A, B, C, D) and state x , a common anomaly-detector strategy is to monitor the innovation signal $r = \tilde{y} - C\hat{x}$, where $\hat{x}$ is the optimal state estimate. Under the null hypothesis that there is no attacker present, the innovation signal is an independent stochastic signal with known statistics. The detector may implement various change detection tests to generate alerts (Basseville 1988). A *stateless* test (Giraldo et al. 2018) raises an alarm every time t that

$$\|r_t\| \geq \tau, \quad (2)$$

where τ is a tunable threshold. A *stateful* non-parametric CUMulative SUM (CUSUM) test (Giraldo et al. 2018) raises an alarm at time t when

$$S_t \geq \tau, \quad (3)$$

where $S_{t+1} = \max(0, S_t + \|r_t\| - \delta)$, $S_0 = 0$. The forgetting factor δ is selected such that the expected value of $\|r_t\| - \delta$ is negative under the null hypothesis. In these tests, the operator should choose the parameters τ and δ such that a reasonable trade-off between the true and false alarm rates is achieved. Because of the possibility of stealth attacks, the true positive alarm rate may very well be zero, however, and tuning could be difficult (see Giraldo et al. (2018) and section “[Impact](#)”). The survey (Basseville 1988)

provides an overview of alternative (parametric) change detection tests. These are often optimal but require more detailed alternative (fault or attack) hypotheses than needed in (2)–(3).

To obtain fundamental limits on detectors, Bai et al. (2017) proposed to study the Kullback-Leibler divergence between the integrity-attacked measurement sequence $\tilde{y}_0^{t-1}(x_0, i_u, i_y)$ and the un-attacked (null hypothesis) sequence $\tilde{y}_0^{t-1}(x_0, 0, 0)$:

$$\lim_{t \rightarrow \infty} \frac{1}{t} D_{KL}(\tilde{y}_0^{t-1}(x_0, i_u, i_y) \parallel \tilde{y}_0^{t-1}(x_0, 0, 0)) \leq \epsilon. \quad (4)$$

The idea is that if ϵ is small, there is no detector test that can simultaneously achieve a high true alarm rate and a low false alarm rate.

If the attacker is aware of the applied detector test statistic, such as (2)–(3) above, he can generate stealth attacks more powerful than the more conservative undetectable attacks. The replay attacks, the stealthy data-injection attacks, and sometimes DoS attacks, discussed in section “[CPS Attack Space](#),” are often designed in this manner.

Impact

In section “[Detectability](#),” we discussed when cyberattacks are hard to detect by the operator. This is an important problem since if the operator is not alerted an attack is in progress, the CPS may sustain severe damage. Indeed, an attacker generally has a goal of disrupting some service in the CPS, and not only to remain undetected. In this vein, it becomes important for both operator and attacker to quantify the maximum possible impact of an attack, without the attacker being detected. For example, if one plots the maximum possible (physical) impact of a stealth attack versus the mean time between false alarms, one obtains a trade-off metric that can be used for tuning detector tests (Giraldo et al. 2018). To compute the maximum possible attack impact on the plant state, subject to not triggering an alarm (2)–(3), tools from optimal control theory can be applied, see, for instance, Mo et al. (2010), Cárdenas et al. (2011), and Teixeira et al. (2015).

Attack Mitigation Strategies

Attack mitigation strategies for the CPS operator are a very active area of research. We will here mention a few general approaches related to the attack strategies discussed in section “[CPS Attack Space](#).”

To prevent *eavesdropping attacks*, encryption and coding methods may be used to protect the information sent over the network. Homomorphic encryption has been proposed as suitable for control systems, (see Kim et al. (2016) and Farokhi et al. (2017)), since it allows for direct computation on encrypted data. Encryption relies on secret keys, whereas coding schemes are generally publicly known but transmit information in a manner that makes it difficult for an eavesdropper to recover the complete data; see Miao et al. (2017) and Wiese et al. (2019), for instance. Another approach is to intentionally corrupt the transmitted data before communication over the network (Leong et al. 2018). A popular privacy notion, deriving from the database literature, is differential privacy; see Cortés et al. (2016). Differential privacy is often achieved by intentionally injecting Laplacian or Gaussian noise.

To mitigate *replay attacks*, the operator may superimpose a watermark signal on the control input and check that its expected effect is present in the received measurement; see Mo et al. (2015), for instance. In a related manner, a multiplicative watermarking signal can be introduced on the sensor output and then removed on the controller side; see Ferrari and Teixeira (2017).

Several approaches have been proposed to counter *stealthy data-injection attacks*. Using the trade-off metric mentioned in section “[Impact](#),” it may be possible to tune detectors such that possible undetected attack impact is at an acceptable level (Giraldo et al. 2018). If this is not possible, additional sensors and signal authentication may be installed to obtain more favorable detector trade-offs. A more reactive form of mitigation is to install so-called secure state estimators (Fawzi et al. 2014). If the operator has enough redundant sensors to ensure undetectable attacks are not possible (see section “[Detectability](#)”), the secure

state estimator can always reconstruct a data-injection attack and compute a correct state estimate. Yet another form of defense is so-called moving target defense (Weerakkody and Sinopoli 2015). The idea is to decrease the attacker’s CPS model knowledge (see Fig. 2) by varying the system’s parameters over time to counter possible system identification by the attacker.

To mitigate the effect of *DoS attacks*, game-theoretic (Ugrinovskii and Langbort 2017), optimal control (Amin et al. 2009), and event-triggered control (Cetinkaya et al. 2017; De Persis and Tesi 2015) approaches have been proposed, for instance.

Summary and Future Directions

We have given a brief introduction to the area of cyber-physical security. We have discussed modeling of cyberattacks targeting networked control systems and how their confidentiality, integrity, and availability may be violated using different attack strategies. Some common attack strategies, namely, eavesdropping attacks, replay attacks, stealthy data-injection attacks, and DoS attacks, were covered in more detail. In allocating defense resources, it is important for the system operator to assess the detectability and impact of attacks, and we discussed some available tools for this. Finally, we gave a brief overview of available attack mitigation strategies.

CPS security is a relatively new research area in the systems and control community. Hence, there are many promising future research directions. It is noteworthy that there are few research papers strongly combining ideas from IT security and control engineering. The reason is most likely that IT security tends to focus on cyber aspects and the use of discrete mathematics, whereas control engineering tends to focus on physical aspects and continuous-time and continuous-state models. However, work that seriously combines ideas from both domains would likely have large impact, also outside of their traditional communities. A promising example along this line is the use of homomorphic encryption in feedback systems.

Another promising area for interdisciplinary work is machine learning and control engineering. Machine learning may be used for data-driven detection and diagnosis of anomalies and attacks. Machine learning is becoming increasingly societally relevant, but there are also privacy issues worth investigation, as well as concerns about vulnerability to integrity attacks. A definite concern is also that many machine learning methods come with few formal guarantees, which are highly desirable in safety-critical CPS applications. In general, investigation of fundamental trade-offs between performance criteria is an interesting problem in CPS security. One example is the trade-off between privacy, security, and control performance when the operator as defense is deliberately injecting noise (“watermarking”) or actively changing the system (“moving target defense”).

Finally, the areas of fault detection, fault-tolerant control, and change detection are well established in control engineering, and many tools developed there have inspired work in CPS security. Nevertheless, there are certainly more connections to be made, for instance, with regard to the diagnosis of root causes of faults and attacks. A key difference between faults and attacks is that the latter are caused by an intelligent agent with a usually malicious incentive. In contrast, faults are generally random and uncoordinated, which potentially make them easier to detect and mitigate.

Recommended Reading

The CPS security knowledge area report (Cardenas 2019) provides a broad and readable introduction to the area, with many references also

to work outside of control engineering. A more control-theoretically focused contribution is the special issue (Sandberg et al. 2015), which contains six articles covering basic topics in CPS security. An early experimental case study on CPS security focusing on control system aspects is Amin et al. (2013).

One of the first papers taking a control-theory approach to analyzing cyberattacks on CPS, namely, replay attacks, is Mo and Sinopoli (2009). The paper Pasqualetti et al. (2013) has been influential and establishes basic concepts such as undetectable attacks (section “[Detectability](#)”) and attack detection mechanism inspired by fault diagnosis tools. The paper Sundaram and Hadjicostis (2011) is another early influential paper, which focuses on distributed attack detection for networks of interconnected nodes. The paper Teixeira et al. (2015) provides a general modeling framework for attacks and defenses in networked control systems (Figs. 1 and 2). The article Fawzi et al. (2014) introduces the secure state estimator as a mitigation strategy, which has been extended in several follow-up works. Finally, a risk-based tutorial introduction to CPS security, with many references to recent work, is Chong et al. (2019).

Cyber-Physical Systems Security: A Control-Theoretic Approach

Yuqing Ni, Ziyang Guo, and Ling Shi
Department of Electronic and Computer Engineering, The Hong Kong University of Science and Technology, Kowloon, Hong Kong, China

Abstract

This entry introduces security issues in cyber-physical systems mainly from two perspectives: one is to analyze the attack effectiveness from the malicious attacker's perspective and the other is to design the attack detection mechanism and control scheme from the system designer's perspective. For the first research aspect, existing works focused on the worst-case performance degradation analysis when the system is under a certain type of attack are introduced, among which *DoS attack* and *integrity attack* are of the

most interest. For the second research aspect, existing works providing countermeasures to detect the existence of attacks and proposing resilient estimation and control methodologies against hostile attacks are introduced. The main framework of cyber-physical systems is provided, and solid results about security issues are reviewed from selected high-quality journal papers in this entry.

Keywords

Cyber-physical system security · DoS attack · Integrity attack · Countermeasure mechanism design

Introduction

Cyber-physical systems (CPSs), which coordinate sensing, computing, communication, and control methods with physical plants, have drawn an enormous amount of attention in the most recent couple of years. A wide scope of applications include power grids, wireless sensor networks, autonomous vehicles, intelligent transportation systems, healthcare and medical systems, environment monitoring systems, etc. (Kim and Kumar 2012). In most CPSs, with the recent advances in wireless technologies, tiny wireless sensors play an indispensable role, well-known for their low cost, easy installation, self-power, and inherent intelligent processing capability (Gungor and Hancke 2009). The wireless communication has been replacing the traditional wired communication between system components, which fundamentally upgrades the system's mobility, scalability, and feasibility.

However, along with the advantages, CPSs are confronted with critical security challenges. The nature of wireless communication and the complex interconnection between the physical layer and the cyber layer make CPSs vulnerable to potential threats. An incident caused by the attack on one system in a single infrastructure at Maroochy Water Services in Queensland is described in Slay and Miller (2007). The terrible Stuxnet virus infected around 100,000

computers mostly in Iran, India, Indonesia, and Pakistan and even showed up in an Iranian nuclear plant (Farwell and Rohozinski 2011). Such security-related incidents suggest that any successful attack may result in disastrous consequences on the national economy, social security, or even human lives. Therefore, the security is of significant importance to guarantee the reliable operation of CPSs.

To evaluate the information security, the established CIA (confidentiality, integrity, and availability) triad is utilized as a benchmark model (Andress 2014). Confidentiality means that the private information is not allowed to be accessed by unauthorized users. Integrity is the property that the data should be accurate and complete. Availability indicates that information should always be available when it is required for the service purpose. According to the system model knowledge, disclosure resources, and disruption resources of the adversary (Teixeira et al. 2015), *eavesdropping*, *denial-of-service (DoS) attack*, *integrity attack*, and physical intrusion which compromise data confidentiality, integrity, or availability are main security threats to the CIA triad in CPSs as shown in Fig. 1. There have been many approaches developed to security based on the features of the CPSs mainly from two different perspectives: one is to analyze the attack effectiveness from the malicious attacker's point of view and the other is to design the attack detection mechanism and the corresponding secure estimation and control scheme from the system designer's perspective. For the first research aspect, existing works mostly concentrate on the worst-case performance degradation analysis when a system is under a certain type of attack, among which *DoS attack* and *integrity attack* are of the most interest. For the second research aspect, most existing works provide countermeasures to detect the existence of attacks and propose robust estimation and control methods against hostile attacks. The detection schemes can be divided into the attack-dependent schemes and the attack-independent schemes. The countermeasure designed specifically for one type of attack is called attack-dependent. Otherwise, it is attack-

Cyber-Physical Systems Security: A Control-Theoretic Approach, Fig. 1 Attack types in cyber-physical systems

independent since it is applicable to different attack scenarios. The complicated situations make it extremely difficult for a system designer to predict the specific attack type beforehand. Consequently, different methodologies should be adopted to design the attack-independent detection mechanism, e.g., the information-theoretic, the control-theoretic, and the optimization-based approaches.

Future research directions of CPSs security are abundant including but not limited to proposing more accurate and practical attack/defend models and analyzing attacker/defender's behavior subject to limited or partial knowledge.

The remainder of the entry is divided into two main sections discussing the attack strategies and defense strategies, respectively.

Notations: $\mathbb{N}$ denotes the set of nonnegative integers. $\mathbb{R}$ denotes the set of real numbers. $\mathbb{R}^n$ is the n -dimensional Euclidean space. For $x \in \mathbb{R}^n$, $\|x\|$ denotes its ℓ_2 norm. $X^\top$, $\text{Tr}(X)$, $\rho(X)$, and X^{-1} stand for the transpose, trace, spectral radius, and inverse of matrix X . $\text{Diag}\{\cdot\}$ denotes the block diagonal matrix. $\mathbb{S}_+^n$ ($\mathbb{S}_{++}^n$) is the set of $n \times n$ positive semi-definite (definite) matrices. When $X \in \mathbb{S}_+^n$ ($\mathbb{S}_{++}^n$), it can be denoted by $X \succeq 0$ ($X \succ 0$). δ_{ij} is the Dirac delta function: $\delta_{ij} = 1$ if $i = j$; $\delta_{ij} = 0$ otherwise. For functions f , f_1 , f_2 , $f_1 \circ f_2$ is defined as $f_1 \circ f_2(X) \triangleq f_1(f_2(X))$, and

f^k is defined as $f^k(X) \triangleq \underbrace{f \circ f \cdots f}_{k \text{ times}}(X)$ with $f^0(X) = X$.

In CPSs, the physical plant is described by a standard discrete-time linear time-invariant (LTI) process:

$$x_{k+1} = Ax_k + Bu_k + w_k, \quad (1)$$

$$y_k = Cx_k + v_k, \quad (2)$$

where $k \in \mathbb{N}$ is the time index, $x_k \in \mathbb{R}^n$ is the process state vector, $u_k \in \mathbb{R}^q$ is the control input, $y_k \in \mathbb{R}^m$ is the measurement collected by the sensor, $w_k \in \mathbb{R}^n$, and $v_k \in \mathbb{R}^m$ are zero-mean i.i.d. Gaussian noises with $\mathbb{E}[w_i w_j^\top] = \delta_{ij} Q$ ($Q \succeq 0$), $\mathbb{E}[v_i v_j^\top] = \delta_{ij} R$ ($R \succ 0$), $\mathbb{E}[w_i v_j^\top] = 0, \forall i, j \in \mathbb{N}$. The initial state x_0 is zero-mean Gaussian with covariance matrix $\Pi_0 \succeq 0$, which is independent of w_k and v_k for all $k \in \mathbb{N}$. Assume that the pair (A, C) is observable and $(A, \sqrt{Q})$ is controllable.

Attack Effectiveness Analysis

DoS Attack

The *DoS attack* aims at blocking the communication channel and preventing legitimate access

between system components. The adversary can either emit a high-strength radio signal to flood the targeted channel or violate network protocols to cause packet collisions (Xu et al. 2006). Since jamming is a power-intensive activity and the available energy or attack capability of a jammer might be limited, *DoS attacks* on estimates for the resource-constrained attacker are investigated in Zhang et al. (2015), Qin et al. (2018), Li et al. (2015a, b), and Ding et al. (2017).

With the development of manufacturing techniques, many modern sensors are equipped with extra functions, e.g., signal processing, decision making, and alarm monitoring, beyond those necessary for generating the measured quantity (Lewis 2004; Hovareshti et al. 2007; Frank 2013). A smart sensor with computational abilities is deployed to pre-estimate the state x_k based on the gathered raw measurement y_k as shown in Fig. 2. The minimum mean squared error (MMSE) estimate $\hat{x}_k^s \triangleq \mathbb{E}[x_k | y_0, y_1, \dots, y_k]$ and the corresponding error covariance

$$\hat{P}_k^s \triangleq \mathbb{E}[(x_k - \hat{x}_k^s)(x_k - \hat{x}_k^s)^\top | y_0, y_1, \dots, y_k]$$

can be calculated by a standard Kalman filter. The Kalman filtering analysis shows that the error covariance converges to a unique positive semi-definite matrix $\bar{P}^s$ from any initial condition (Bertsekas 1995). In practice, the Kalman gain usually converges in a few steps. For brevity, it is assumed that $\hat{P}_0^s = \bar{P}^s$. Define the Lyapunov operator $h : \mathbb{S}_+^n \rightarrow \mathbb{S}_+^n$ as $h(X) \triangleq AXA^\top + Q$. It is shown that the optimal state estimate $\hat{x}_k$ and the corresponding error covariance $\hat{P}_k$ at the remote estimator have the following recursive form according to the estimate $\hat{x}_k^s$ received from the smart sensor (Schenato 2008):

$$\hat{x}_k = \begin{cases} \hat{x}_k^s, & \text{if } \hat{x}_k^s \text{ is received at the remote} \\ & \text{estimator,} \\ A\hat{x}_{k-1}, & \text{otherwise,} \end{cases} \quad (3)$$

$$\hat{P}_k = \begin{cases} \bar{P}^s, & \text{if } \hat{x}_k^s \text{ is received at the} \\ & \text{remote estimator,} \\ h(\hat{P}_{k-1}), & \text{otherwise.} \end{cases} \quad (4)$$

In Zhang et al. (2015), the attacker's decision variable $\gamma_k = 1$ or 0 means launching a *DoS attack* or not at time k . If a *DoS attack* is launched, the data packet transmitted from the smart sensor to the remote estimator will be dropped with probability $0 < \alpha < 1$. The problem of interest for the attacker is to determine an attack strategy $\{\gamma_k\}$ under some energy constraint, such that the average expected estimation error covariance matrix at the remote estimator is maximized during a finite time horizon T . The energy constraint only enables the attacker to launch T_0 attacks from $k = 1$ to $k = T$ where $T_0 < T$. The optimization problem is given by:

Problem 1

$$\begin{aligned} \max_{\{\gamma_k\}} J &= \frac{1}{T} \sum_{k=1}^T \text{Tr}(\mathbb{E}[\hat{P}_k]), \\ \text{s.t. } \sum_{k=1}^T \gamma_k &= T_0. \end{aligned}$$

It is proved in Zhang et al. (2015) that the optimal attack strategy is to launch *DoS attacks* consecutively for T_0 times which can start at any time in the interval $[1, T - T_0 + 1]$, and the corresponding cost is as follows:

$$\begin{aligned} J_{\max} &= \frac{1}{T} \sum_{i=1}^{T_0} \left[(T_0 - i) (\alpha^i - \alpha^{i+1}) + \alpha^i \right] \\ &\quad \text{Tr}(h^i(\bar{P}^s)) + \frac{T - \alpha T_0}{T} \text{Tr}(\bar{P}^s). \end{aligned} \quad (5)$$

Furthermore, a packet-dropping network is considered in Qin et al. (2018). When there is not any *DoS attack*, the data packet transmitted from the smart sensor to the remote estimator will be dropped with probability β , where $0 < \beta < \alpha < 1$. The optimal attack solution to Problem 1 is characterized by Fig. 3, where $T_1 + T_2 = T - T_0$, and

Cyber-Physical Systems**Security:****A Control-Theoretic****Approach, Fig. 2** *DoS*

attack on estimates in
cyber-physical systems

Cyber-Physical Systems Security: A Control-Theoretic Approach, Fig. 3 Optimal *DoS* attack with dropping network

$$\begin{aligned} \max_{\theta_A} J &= \frac{1}{T} \sum_{k=1}^T \text{Tr} \left(\mathbb{E} \left[\hat{P}_k \right] \right), \\ \text{s.t. } \sum_{k=1}^T \gamma_k &= T_0^A. \end{aligned}$$

$|T_1 - T_2| \leq 1$, which is a little different from the optimal solution in Zhang et al. (2015).

Instead of focusing only on the attacker, game-theoretic approaches are adopted to investigate the interactive decision-making process between the DoS attacker and the system in Li et al. (2015b). The DoS attacker's jamming strategy is denoted as $\theta_A \triangleq \{\gamma_1, \gamma_2, \dots, \gamma_T\}$ and $\sum_{k=1}^T \gamma_k \leq T_0^A$. Similarly, the sensor's data-sending strategy is denoted as $\theta_S \triangleq \{\lambda_1, \lambda_2, \dots, \lambda_T\}$ and $\sum_{k=1}^T \lambda_k \leq T_0^S$. It is assumed that the dropout probability of data packet from the smart sensor to the remote estimator is β in the absence of attack and is α ($> \beta$) under the *DoS* attack. The problem of interest in a game-theoretic framework is given by:

Problem 2 For the sensor,

$$\begin{aligned} \min_{\theta_S} J &= \frac{1}{T} \sum_{k=1}^T \text{Tr} \left(\mathbb{E} \left[\hat{P}_k \right] \right), \\ \text{s.t. } \sum_{k=1}^T \lambda_k &= T_0^S. \end{aligned}$$

For the attacker,

It is proved in Li et al. (2015b) that there exists a Nash equilibrium for the considered two-player zero-sum game between the sensor and the attacker. For the case where the two players have online information about the previous transmission outcomes and the occurrence of *DoS* attacks, an algorithm is provided to perform the game dynamically.

A Markov game between the sensor and the attacker with multiple channels under a signal-to-interference-and-noise-ratio (SINR)-based network model is studied in Ding et al. (2017), and a modified Nash Q-learning algorithm is applied to obtain the Nash equilibrium. In Ding et al. (2019), an asymmetric-information-structured game framework is constructed to study the interaction between a sensor and a DoS attacker. It is assumed that the acknowledgment information from the remote estimator to the sensor is hidden from the DoS attacker. The game is converted into a continuous-state one and solved by the multi-agent reinforcement learning method.

Integrity Attack

Integrity attack is also called deception attack. The studies of *integrity attack* can be divided into the control attack analysis and the measurement attack analysis as shown in Fig. 4. Three main *integrity attack* types will be introduced: *replay attack*, *false-data injection*

attack, and *innovation-based integrity attack*. Besides, there are many other *integrity attack* types, e.g., GPS spoofing, time synchronization attack, reset attack, and so on.

For the system, a linear quadratic Gaussian (LQG) controller minimizing the following objective function is considered:

$$J_{LQG} = \min_{\{u_k\}} \lim_{T \rightarrow \infty} \frac{1}{T} \mathbb{E} \left[\sum_{k=0}^{T-1} \left(x_k^\top W x_k + u_k^\top U u_k \right) \right], \quad (6)$$

where $W \succeq 0$, $U \succeq 0$, and u_k are measurable with respect to $y_0, \dots, y_k$. The optimal solution is a fixed gain controller: $u_k = L\hat{x}_k$. It is assumed that the pair (A, B) is controllable and $(A, \sqrt{W})$ is observable. Besides, a false-data detector is deployed at the estimator side to monitor system behavior and detect the existence of potential malicious attacks. Note that innovation $z_k = y_k - C\hat{x}_k^-$, where $\hat{x}_k^- \triangleq A\hat{x}_{k-1}^s$, has a steady-state Gaussian distribution $\mathcal{N}(0, \Sigma)$. A χ^2 detector (Mehra and Peschon 1971) makes a decision based on the sum of the normalized innovation sequence, i.e., at time k , the detection criterion follows a hypothesis testing:

$$g_k = \sum_{i=k-D+1}^k z_i^\top \Sigma^{-1} z_i \underset{H_1}{\overset{H_0}{\leq}} \sigma, \quad (7)$$

where D is the detection window size, σ is the threshold, and the null hypothesis H_0 stands for the normal operation of the system, while the alternative hypothesis H_1 means that the system is under attack.

Replay Attack

As one of the *integrity attacks*, the *replay attack* does not require any system knowledge. It attempts to inject exogenous control inputs while repeating historical measurements to maintain stealthiness to the false-data detector. In Mo and Sinopoli (2009), it is assumed that the attacker can inject a control input into the system anytime, and it knows all the measurements, with the ability to modify them at the same time. After recording a sufficient number of measurements without giving any input to the system, the

attacker can launch a *replay attack* by injecting a sequence of desired control input while replaying the previously recorded measurements. The χ^2 detector turns out to be useless for the system if $(A + BL)(I - KC)$ is stable, where K is the steady Kalman filter gain, which means that the detection rate of the system converges to the false alarm rate.

False-Data Injection Attack

The *false-data injection attack* needs to be launched with full system knowledge. In Mo and Sinopoli (2010), a control system with a Kalman filter, an LQG controller, and a χ^2 detector with the detection window size $D = 1$ is considered. It is assumed that the attacker knows system matrices A, B, C, Q , and R and the Kalman gain K and the LQG gain L , where $A - KCA$ and $A + BL$ are both stable. As its name implies, the *false-data injection attack* is launched by injecting a malicious input y_k^a from time $k = 0$:

$$y_k = Cx_k + v_k + \Theta y_k^a, \quad (8)$$

where $\Theta \triangleq \text{Diag}\{\theta_1, \dots, \theta_m\}$ is the sensor selection matrix and θ_i s are binary variables. Define Δx_k , Δz_k , and Δe_k as the state, the innovation, and the estimation error differences between the partially compromised system and the healthy system, respectively. A control system is *perfectly attackable* if there exists an attack sequence $\{y_k^a\}$ such that $\limsup_{k \rightarrow \infty} \|\Delta x_k\| = \infty$, $\|\Delta z_k\| \leq 1$ for all $k \in \mathbb{N}$. Intuitively, it implies that the *false-data injection attack* could destabilize the system while successfully bypassing a large set of possible false-data detectors. A necessary and sufficient condition

Cyber-Physical Systems**Security:****A Control-Theoretic****Approach,****Fig. 4** Integrity attack in cyber physical systems

for a system to be *perfectly attackable* is derived as follows:

Theorem 1 A control system (1) is *perfectly attackable* if and only if A has an unstable eigenvalue and the corresponding eigenvector v satisfies:

1. $Cv \in \text{span}(\Theta)$, where $\text{span}(\Theta)$ is the column space of Θ ;
2. v is a reachable state of the dynamic system $\Delta e_{k+1} = (A - KCA)\Delta e_k - K\Theta y_{k+1}^a$.

Similarly in Hu et al. (2018), a system is called *insecure* if there exists an attack sequence $\{y_k^a\}$ such that $\lim_{k \rightarrow \infty} \|\Delta \hat{x}_k\| \rightarrow \infty$ and $\|\Delta z_k\|$ is upper bounded by a prescribed small positive constant scalar for all $k \in \mathbb{N}$, where $\Delta \hat{x}_k$ is the estimate difference between the partially compromised system and the healthy system. It is proved that the system is *insecure* if and only if the spectral radius of A is not less than 1, under the assumption that the attacker can inject malicious input to all the sensors, i.e., $\Theta = I$.

In Mo and Sinopoli (2016), an adversary attempts to induce perturbation in CPSs by compromising a subset of the sensors and injecting an exogenous control input while remaining undetected by the false-data detector. To analyze the control system's estimation

performance degradation under the *false-data injection attack*, a constrained control problem is formulated. The characterization of the maximum perturbation induced is posed as a reachable set computation problem, which can be solved by ellipsoidal calculus.

A *false-data injection attack* with control objectives in analyzed in Chen et al. (2018). The CPS model under the attack is as follows:

$$x_{k+1} = Ax_k + Bu_k + w_k + \Gamma d_k, \quad (9)$$

$$y_k = Cx_k + v_k + \Psi d_k, \quad (10)$$

where $d_k \in \mathbb{R}^s$ is the attack injection, and matrices Γ and Ψ model the attacker. The problem of interest is to drive the system state to a target value x^* while remaining undetected from a χ^2 detector to the best of the attacker's ability. The attacker's quadratic cost function is a linear combination of components penalizing the distance from the target state and the energy of the system's detection statistic. A closed-form optimal attack solution $\{d_k\}$ is obtained by dynamic programming.

Besides the χ^2 detector, the Kullback-Leibler (KL) divergence, a nonnegative measure of the distance between two probability distributions, is also well-known in detection

theory. *False-data injection attack* against the KL divergence detector is studied in Bai et al. (2015, 2017a, b) and Kung et al. (2017). Specifically, an ϵ -stealthy *false-data injection attack* on the control input u_k for first-order control systems is studied in Bai et al. (2015), where the KL divergence between the compromised innovation and the true innovation, i.e., $\mathcal{D}(\tilde{z}_1^k \| z_1^k)$, is adopted as a stealthiness metric. For high-dimensional dynamic control systems, more advanced results are reported in Bai et al. (2017a) and Kung et al. (2017). In Bai et al. (2017a), the optimal ϵ -stealthy attack on the control input which induces the largest estimation performance degradation is obtained for right invertible systems, and a suboptimal attack solution is obtained for right non-invertible systems. In Kung et al. (2017), the achievable upper bound of the average estimation error covariance by an ϵ -stealthy attack is derived when the observation matrix $C \in \mathbb{R}^{m \times n}$ is full rank and $m \geq n$. When C is full rank and $m < n$, there exists an ϵ -stealthy attack such that the induced average estimation error covariance can be arbitrarily large. A *false-data injection attack* on measurement y_k for first-order systems under the ϵ -stealthy metric is investigated in Bai et al. (2017b).

Innovation-Based Integrity Attack

The *integrity attacks* mentioned above are all focused on control input u_k and measurement y_k . Integrity attacks on innovation z_k are introduced as follows. An optimal linear *innovation-based integrity attack* is proposed in Guo et al. (2017). It considers a remote estimation scenario where a sensor measures a linear dynamic system and transmits its local innovation z_k to a remote estimator through a wireless network. There exists a malicious attacker who is able to intercept and modify the transmitted z_k . A χ^2 false-data detector is deployed at the remote estimator side to check data anomalies. A specific affine attack strategy is $\tilde{z}_k = T_k z_k + b_k$ where $T_k \in \mathbb{R}^{m \times m}$ is an arbitrary matrix and $b_k \in \mathbb{R}^m$ is a zero mean i.i.d. Gaussian random variable with covariance L_k and independent of z_k . Since the original innovation z_k has a steady-state Gaussian distribution $\mathcal{N}(0, \Sigma)$, $\tilde{z}_k$ is supposed to satisfy the

same Gaussian distribution $\mathcal{N}(0, \Sigma)$ to bypass the false-data detector, i.e.,

$$T_k \Sigma T_k^\top + L_k = \Sigma, \quad (11)$$

which is equivalent to $L_k = \Sigma - T_k \Sigma T_k^\top \geq 0$. It is proved in Guo et al. (2017) that the optimal stealthy attack strategy which yields the largest remote estimation error covariance is $T_k^* = -I$ and $b_k^* = 0$. Intuitively, the estimation error covariance is maximized when the attacker just inverts the innovation sequence. Besides, the ϵ -stealthy innovation-based affine *integrity attack* against the KL divergence is analyzed in Guo et al. (2018). Denote the estimation error covariance at the remote estimator under such affine *innovation-based attack* as $\tilde{P}_k$ and the problem of interest for the attacker is as follows:

Problem 3

$$\begin{aligned} \max_{T_k, b_k} \quad & \text{Tr}(\tilde{P}_k) \\ \text{s.t.} \quad & \mathcal{D}(\tilde{z}_k \| z_k) \leq \epsilon, \quad \forall k. \end{aligned}$$

By solving a two-stage optimization problem, the worst-case linear attack strategy is proved to be zero-mean Gaussian distributed.

Countermeasure Mechanism Design

As mentioned above, one way to investigate the security in CPSs is to focus on specific types of attacks, and the other way is to design detection schemes and build attack-resilient systems.

A transmission scheduling for remote state estimation in the presence of an eavesdropper is proposed in Leong et al. (2019). As shown in Fig. 5, let $\lambda_k \in \{0, 1\}$ be system's decision variables such that $\lambda_k = 1$ if and only if $\hat{x}_k^s$ is to be transmitted at time k . If the local estimate $\hat{x}_k^s$ is transmitted, it will be successfully received by the remote estimator with probability ζ and overheard by the eavesdropper with probability ζ_e , where the stochastic transmission processes for both the remote estimator and the eavesdropper are mutually independent. The problem of

Cyber-Physical Systems Security: A Control-Theoretic Approach, Fig. 5 Remote estimation with an eavesdropper in cyber-physical systems

interest for the system designer is to minimize the expected error covariance $\hat{P}_k$ at the remote estimator while trying to keep the expected error covariance $\hat{P}_{e,k}$ at the eavesdropper above a certain level:

Problem 4

$$\min_{\{\lambda_k\}} \sum_{k=1}^T \mathbb{E} \left[\varepsilon \text{Tr}(\hat{P}_k) - (1 - \varepsilon) \text{Tr}(\hat{P}_{e,k}) \right],$$

for some $\varepsilon \in (0, 1)$. In the case where the transmission decision λ_k depends on the error covariances of both the remote estimator $\hat{P}_{k-1}$ and the eavesdropper $\hat{P}_{e,k-1}$, the optimal solution to Problem 4 is a nondecreasing threshold policy on $\hat{P}_{k-1}$ for fixed $\hat{P}_{e,k-1}$. Suppose that A is unstable and that $\zeta > 1 - \frac{1}{\rho^2(A)}$. Then it is also proved in Leong et al. (2019) that for any $0 < \zeta_e < 1$, there exist transmission policies in the infinite horizon situation such that $\limsup_{T \rightarrow \infty} \frac{1}{T} \sum_{k=1}^T \text{Tr}(\mathbb{E}[\hat{P}_k])$ is bounded and $\liminf_{T \rightarrow \infty} \frac{1}{T} \sum_{k=1}^T \text{Tr}(\mathbb{E}[\hat{P}_{e,k}])$ is unbounded. Intuitively, the system designer can make the estimation error covariance at the eavesdropper diverge while keeping its own estimation error covariance bounded, which shows the defense ability of the system designer to the *eavesdropping*. Besides preserving information from the malicious eavesdropper, sometimes each sensor should also prevent undesirable disclosure of information to the other sensors in the network, which is called the privacy. In Mo and Murray (2017), a privacy preserving average consensus

algorithm is proposed to guarantee the privacy of the initial state and asymptotic consensus on the exact average of the initial values, by introducing random noises to the consensus process.

For the *replay attack* proposed in Mo and Sinopoli (2009), a physical watermarking strategy is introduced as a countermeasure, and the optimal watermark authentication signal is derived in Mo et al. (2015), and the trade-off between estimation quality and detection rate is analyzed under a stochastic game-theoretic framework in Miao et al. (2013). For noiseless dynamic systems under *false-data injection attacks* on control inputs or measurements, Fawzi et al. (2014) characterizes the maximum number of attacks that can be detected and corrected. It is shown that if more than half the sensors are corrupted, it is impossible to accurately reconstruct the system's state. The results are further extended to systems with noise and modeling errors in Pajic et al. (2014) and Mishra et al. (2017). Since locating the sensors under *false-data injection attacks* is essentially a combinatorial problem, a satisfiability modulo theory-based method for secure state estimation is proposed in Shoukry et al. (2017), where the scalability, soundness, and completeness of the proposed algorithm are analyzed. In Shi et al. (2018), transfer entropy-based causality countermeasures are investigated for both sensor measurements and innovation sequences. The countermeasures are shown to be related to the system parameters, based on which the convergence condition is analyzed and the effectiveness is evaluated. In Mo and Garone

(2016), for the scenario where a subset of the sensors are under *false-data injection attacks*, a convex optimization-based data fusion approach is adopted to combine the local estimates into a more secure state estimation. A more general convex optimization-based estimator with an ℓ_1 penalty is considered in Han et al. (2016), and necessary and sufficient conditions for resilience are analyzed with a trivial gap. A stochastic modeling framework for secure state estimation is introduced in Shi et al. (2017), based on which the attacked system is modeled as a finite-state hidden Markov model. Under this framework, a joint state and attack estimation problem are formulated and solved. In Guo et al. (2019), a modified Gaussian mixture model (GMM)-based detection algorithm is proposed to locate the compromised sensors and obtain an accurate state estimate in a situation where a subset of sensors are under *integrity attacks* from a malicious attacker. The algorithm can autonomously cluster the sensors and fuse the measurements based on different beliefs. For the *innovation-based integrity attack* introduced in Guo et al. (2017) with multiple sensors, three sequential data verification and fusion procedures for different detection information scenarios based on the information extracted from the trusted sensors and correlations among the sensors are proposed in Li et al. (2019).

Abstract

Cyber-physical-human systems (CPHS) is an emerging field where the human, the physical system, and enabling cyber technologies are interconnected through complex interactions to accomplish a certain goal. This sharply contrasts with a conventional perspective where the human is treated as an isolated element who operates or uses the system. In this entry, we provide a general introduction to CPHS and present representative examples from the recent literature. CPHS is a growing field, and currently there are no agreed upon definitions about what constitutes a CPHS or not. Therefore, the entry mainly reflects the authors' current understanding of the topic.

interaction

Introduction

Systems and control has always been a broad and abstract discipline. It has progressed, thrived, and flourished due to its ability to reinvent, reconfigure, and reorient its vistas of theoretical inquiries and technological advances. As several surveys, reports, and position papers (Murray 2003; Samad and Annaswamy 2011, 2014; Lamnabhi-Lagarrigue et al. 2017) have clearly articulated, the need for control systems has been reinforced through societal grand challenges in health and medicine, energy and climate, sustainability and development, and productivity and economic growth, to name a few. New frontiers are continuing to emerge, in application-centric directions such as Internet of Things and Industry 4.0, theoretical directions such as machine learning and data science, and conceptual directions such as cyber-physical-human systems (CPHS). The focus of this entry is on the last item, CPHS.

Significant advances in automation, communications, and computing have formed the foundation of the field of cyber-physical systems (CPS). As societal challenges increase, there is an increasing need for human elements to form closer ties with CPS. The underlying interactions and integrations of CPS and human systems are varied, complex, and highly challenging and merit a systematic investigation, forming the underpinning of CPHS.

The common thread between automation and human systems has a long and rich history and can perhaps be traced to the notion of cybernetics, if not even earlier. As Wiener postulates in his magnum opus (Wiener 1948), it is the scientific study of how humans, animals, and machines control and communicate with each other. The fundamental tenets of automation – steer, navigate, and govern – pervade intelligence, resilience, and several other high levels of

functioning in an uncertain environment. These same tenets are attributes of a human system as well. One can perhaps view CPHS as a new incarnation of cybernetics, with more fleshed-out roles for humans to play in specific application areas such as ground transportation, aerial platforms, and robotics, to name a few.

Let's start with an apt example of a CPHS, an automobile with varying levels of autonomy. Per the SAE J3016 standards, levels 0 through 5 are defined (ASME 2018), based on increasing levels of automation, with the roles of the human and automation, driver support features, and automated driving features defined. While much of the focus in this taxonomy is on the machine side, the human modeling component or the requisite interface between human and automation is only now beginning to be investigated. As we move from Level 2 to 3 and higher, the CPHS aspects become increasingly important. How the combined human-automation system performance, robustness, and safety can be addressed so that the resulting system exceeds what would be achievable by either a human or an automation acting alone is an important research direction that should be addressed by our research community. A second example is also a transportation one, in air, where the decision-makers involve a skilled human (i.e., a pilot) and automation (i.e., an autopilot) and the focus is on their combined interaction in the context of emergencies. Here too, the goal is to design the underlying CPHS to realize a performance that would exceed what may be achievable by the human or automation alone. Several other examples can be drawn, from energy (e.g., participation of consumers allowing power consumption to be flexible and on-demand), robotics (e.g., assistance to elders and to differentially abled humans), and manufacturing (congruence between skilled operators and automation).

The examples above illustrate the changing and nuanced nature of interactions between humans and CPS. Humans are no longer passive consumers or actors in these examples; they are empowered decision-makers and drive the evolution of the technology. While notions such as humans-in-the-loop have been around for a few decades, they are transforming with technological

advances. With a parallel development occurring in data analytics and AI research in human decision-making, human-technology coevolution is likely to lead to a very high impact research. Whether in-the-loop, on-the-loop, for-the-loop, or any combinations thereof, these combined interactions between humans and CPS need to be collectively studied, under the rubric of CPHS. The introduction of humans as a key component in the underlying system necessitates new tools, which are grounded in social sciences. Notions of human resilience have been studied in the area of cognitive systems, and concepts such as capacity for maneuver (CfM) and graceful command degradation (GCD) (Woods 2015) appear to have important roles to play in the design of CPHS. Human decision-making under uncertainty has been addressed very elegantly using the notion of prospect theory in the Nobel Prize-winning work of Kahneman and Tversky, which too is beginning to be increasingly employed in the energy and transportation systems modeling and control. Intrinsic to several scenarios in CPHS are interactions between multiple decision-makers that need to be strategic, necessitating the deployment of tools from game theory. In addition to strategic decisions, long-term or time-extended decisions may be called for and may have to be made in the presence of uncertainties. This implies that some form of learning may be useful, which leads to yet another intensely popular tool used of late – reinforcement learning. In this entry, we first elaborate on how prospect theory, game theory, reinforcement learning, and capacity for maneuver concept are used to model humans. Then, we provide specific examples where these tools are actively employed to model the underlying CPHS.

The Human Element in CPHS

The first challenge in CPHS is modeling. Apart from the intricacies of cyber-physical system (CPS) modeling, the human element is even more difficult to model in terms of forecasting their behavior. In this section, we introduce three different tools that are used to predict human actions within CPHS setting.

Prospect Theory

Many of the roles that humans play in CPS may be due to discrete actions rather than continuous ones. Typical examples concern a decision-making that consists of choosing one option out of many. In many infrastructures such as in transportation and energy, such decision-making is quite common and essential to ensure resource allocation and balance of supply and demand. The underlying theory that is often used to model such decision-making is the expected utility theory (EUT) (Ben-Akiva et al. 1985). Briefly, EUT can be explained as follows: Consider a problem where consumers have several travel modes. Utility theory postulates that they choose a travel mode based on optimization of the corresponding utility U of that travel mode. Suppose in a specific travel mode, U takes on discrete values $u_i \in \mathbb{R}, \forall i \in \{1, \dots, n\}$ where n is the number of possible outcomes, with u_i and p_i denoting the utility and probability of outcome i , respectively, with $\sum_{i=1}^n p_i = 1$. Then, one can determine the overall utility function as $U^o = E[U]$, where $E[\cdot]$ denotes the expectation operator, and compute U^o as (Von Neumann and Morgenstern 2007)

$$U^o = \sum_{i=1}^n p_i u_i \quad (1)$$

An interesting method that has been garnering increased attention of late for decision-making in the presence of multiple choices is cumulative prospect theory (CPT) (Tversky and Kahneman 1992; Kahneman and Tversky 2013). This method is appropriate when the underlying problem involves subjective human decision-making in the presence of uncertainty and risk. The behavioral model is described by a value function $V(\cdot)$ and a probability distortion function $\pi(\cdot)$, defined as follows (Tversky and Kahneman 1992; Prelec 1998):

$$V(u) = \begin{cases} (u - R)^{\beta^+} & \text{if } u \geq R \\ -\lambda(R - u)^{\beta^-} & \text{if } u < R \end{cases} \quad (2)$$

$$\pi(p) = e^{-(-\ln(p))^\alpha} \quad (3)$$

In the above, $u(x)$ denotes the utility function for an outcome x , and the nonlinearity $V(\cdot)$

introduces an asymmetry depending on whether or not the utility exceeds a certain reference R , which can be equated with a gain (if $u \geq R$) and a loss (if $u < R$). The parameter λ captures loss aversion and is typically greater than unity, $0 < \beta^+ < \beta^- < 1$ denotes diminishing sensitivity in gains compared to losses, and the parameter α indicates a distorted perception of probability, with low probabilities amplified and high probabilities attenuated. With these two non-linearities, the subjective utility of the outcome x , as perceived by the consumers, is given by

$$U_{PT} = \pi(p)V(u) \quad (4)$$

according to prospect theory, rather than the objective utility pu .

When multiple outcomes are present, a cumulative approach has to be taken in order to evaluate the distorted probability. Suppose that k out of the n outcomes are losses and the rest are gains. That is, $u_i < R$ if $1 \leq i \leq k$ and $u_i \geq R$ if $k < i \leq n$, and $F(U)$ is the cumulative distribution function of U . Then the perceived probability of outcome u_i with the probability p_i is given by (Von Neumann and Morgenstern 2007)

$$w_i = \begin{cases} \pi[F(u_i)] - \pi[F(u_{i-1})], & \text{if } i \in [1, k] \\ \pi[1 - F(u_{i-1})] - \pi[1 - F(u_i)], & \text{otherwise} \end{cases} \quad (5)$$

The subjective utility U^s perceived by the passenger within the CPT framework is given by

$$U^s = \sum_{i=1}^n w_i V(u_i). \quad (6)$$

Capacity for Maneuver Concept

A recent method in modeling of humans under anomalous events utilizes the capacity for maneuver (CfM) concept (Farjadian et al. 2016, 2017, 2020). CfM refers to the remaining range of the actuators before saturation, which quantifies the available maneuvering capacity of the vehicle. One example of the CfM is of the form $CfM = u_{\max} - \text{rms}(u(t))$, where $u_{\max}$ and $u(t)$ refer to the maximum available actuator deflection and actuator deflection at time t , respectively (Eraslan et al. 2020). It is hypothesized that surveillance and regulation of a system's available capacity to respond to all events help maintain the resiliency of a system, which is a necessary merit to recover from unexpected and abrupt failures or disturbances (Woods 2018). Below, two different types of human pilot models, both of which use CfM, are explained.

Perception Trigger

Here, the pilot model is assumed to assess the CfM and implicitly compute a perception gain,

K_t , based on the CfM. The perception algorithm for the pilot is

$$K_t = \begin{cases} 0, & |F_0| < 1 \\ 1, & |F_0| \geq 1 \end{cases} \quad (7)$$

where

$$F_0 = G_1(s)[F(t)], \quad (8)$$

and

$$F(t) = \frac{\frac{d}{dt}(\text{CfM}) - \mu_p}{3\sigma_p}. \quad (9)$$

$G_1(s)$ is a filter introduced as a smoothing and lagging operator into human perception algorithm and $F(t)$ is the perception variable. μ_p and σ_p are the average and the standard deviation of $\frac{d}{dt}(\text{CfM})$. The hypothesis is that the human pilot has such a perception trigger, K_t , and when $K_t = 1$ the pilot takes over control from the autopilot (Farjadian et al. 2016).

CfM-GCD Trade-off

Here, the pilot is assumed to implicitly assess the available CfM when an anomaly occurs and decide on the amount of graceful command degradation (GCD) that is allowable so as to let the CfM become comparable to a certain desired value. Degradation of the command, or the control input, can be implemented by setting a certain autopilot parameter by the pilot. In other

words, it is assumed that the pilot is capable of assessing the suitable value of a certain autopilot control parameter and inputs this value to the autopilot following the occurrence of an anomaly (Farjadian et al. 2020).

Game Theory and Reinforcement Learning

The difficulty of predicting human actions intensifies when the system contains more than one human, which requires factoring in multiple human-human and human-CPS interactions. For example, human interactions are generally not deterministic in nature, which can be projected into CPHS models by utilizing a probabilistic modeling framework. Furthermore, before taking an action, a human generally contemplates other intelligent agents' possible actions and then tries to choose a move that will increase the chances of obtaining the best outcome, which is called "strategic behavior" (Camerer 2011). Finally, humans do not always act in an optimal fashion. This final point is important for distinguishing CPHS models from autonomy models, where, based on available information, an algorithm can possibly be designed to react in the most appropriate way.

Game Theory

Game theory studies the interactions between strategic agents. "Players" in a game theoretical setting refer to the entities who can affect the game by their "moves." "Strategy" of a player defines the procedure based on which a player chooses his or her actions. A "solution concept" is a well-established set of rules that are used to predict how a game will unfold. A "Nash Equilibrium" is a solution concept, defined similarly to the equilibrium in system dynamics: When players have no incentive to deviate from their selected actions, the game is said to be in Nash Equilibrium. This means that in Nash Equilibrium, players choose their best actions against each other's actions. There are other equilibrium concepts such as "quantal response equilibrium" where instead of giving the best response to other players' actions, the players choose a probability distribution over their action space where actions

with higher expected payoffs have higher probability of being played.

Not all solution concepts predict an equilibrium. For example, "level-k thinking" is a non-equilibrium model, which assigns different levels of "reasoning" for players (Stahl and Wilson 1995; Costa-Gomes et al. 2009). In this model, the lowest level of reasoning is level-0, which represents non-strategic thinking, simply meaning that the players who reason at this level have a strategy that does not take into account other players' possible actions. A level-1 player, on the other hand, takes the best action assuming that his or her opponents are level-0 players. Similarly, a level-k player responds best to his *belief* that the other players are reasoning at level-(k-1). Therefore, this model assumes an *iterated* best response (Crawford 2008).

Reinforcement Learning

In RL, there exists an "agent" capable of exerting "actions" that can change the "state" of the environment where the agent operates. The RL problem can be defined as finding the optimal set of action sequence for an agent to achieve a given goal defined as a function of the environment states, through interaction with the said environment (Sutton and Barto 2018).

RL uses the idea of a "reward function" to describe the preferences of the agent while its learning to achieve a predetermined goal. A "policy" is defined as a map from states to actions. The task of the RL algorithm is to find a policy that will make the agent maximize a cumulative discounted reward expressed as

$$C = \sum_{t=0}^{\infty} \gamma^t r_t, \quad (10)$$

where γ is the discount factor and r is the reward obtained in every step t . There are various RL techniques proposed to discover action sequences that will attain the goal of maximizing (10). Almost all of these different methods are based on estimating the "value function," which is the value of being in a certain state, s , based on the policy, π . A value function is given as

$$V^\pi(s) = E_\pi \left\{ \sum_{k=0}^{\infty} \gamma^k r_{t+k} | s_t = s \right\}, \quad (11)$$

where E refers to expected value. The “action value function” is defined as the value of taking a certain action a , in a given state s , and is defined as

$$Q^\pi(s, a) = E_\pi \left\{ \sum_{k=0}^{\infty} \gamma^k r_{t+k} | s_t = s, a_t = a \right\}. \quad (12)$$

The aim of RL is to find the optimum policy π^* that will maximize the value function. The optimal value function is written as V^{π^*} , and all its state values are larger than or equal to that of all other value functions that are created by policies different than the optimal policy. This can be represented as $V^{\pi^*}(s) \geq V^\pi(s), \forall \pi, \forall s$. Similarly, we can write $Q^{\pi^*}(s, a) \geq Q^\pi(s, a), \forall \pi, \forall (s, a)$, for the optimal action value function. Once the optimal action value function is found, the following method can be used to select the best action in each state.

$$\pi^*(s) = \arg \max_a Q^{\pi^*}(s, a). \quad (13)$$

The process of finding the optimal policy is called “training.” During training, the agent observes the states and produces an action based on the observed states. This action influences the environment and results in a new set of states. These new states are evaluated by the reward function, and a reward signal is formed. The agent uses this signal to update the action value function, and the next cycle starts with the new action.

One of the RL methods that played a significant role for the success of RL is “Q-learning” (Watkins 1989). In Q-learning, an incremental estimate of the optimal action value function is realized using the following update rule.

$$\begin{aligned} Q_{k+1}(s_t, a_t) = & Q_k(s_t, a_t) \\ & + \alpha \left(r_t + \gamma \max_a Q_k(s_{t+1}, a) \right. \\ & \left. - Q_k(s_t, a_t) \right). \end{aligned} \quad (14)$$

Merging Game Theory and Reinforcement Learning to Model Human Interactions

For human interactions that last long periods of time, using equilibrium-based game theoretical solutions may be computationally infeasible. One way around this problem is using the non-equilibrium game theoretical solution concept, level- k thinking, explained in section “[Game Theory](#).” This means that once the “anchoring” level, level-0, is selected, a level-1 human agent’s behavior can be identified as the best response to all the other human actions that are determined by the level-0 policy. Similarly, once level-1 behavior is identified, all the agents in the system are assigned the level-1 policy except the one whose level-2 behavior is to be found. Therefore, to predict the policy of a level- k agent, all the rest of the agents’ policies are set to level- $(k-1)$, which effectively make them a part of the environment whose dynamics are known, and level- k policy is determined as the best response to the rest of the level- $(k-1)$ policy actions. This isolates the level- k policy as the single policy that needs to be computed. Once the difficulty of high computational cost due to multiple decision-makers is solved using level- k thinking, the problem reduces to estimating the optimal action sequence of an intelligent agent in a given environment. This problem can be stated as a reinforcement learning (RL) problem by properly defining the states, actions, the environment, and the reward function. The algorithm used in obtaining the agent policies, demonstrating the interplay between the game theory and RL, is provided in Algorithm 1 (Albaba and Yildiz 2019), where k is the maximum desired level.

Interconnecting Humans and Cyber-Physical Systems: Examples of CPHS

Prospect Theory Examples

We describe two examples below where prospect theory has been explored, the first of which is in power grids and the second is in ride-sharing services.

Algorithm 1 Merging RL and game theory

```

1: Set  $i = 0$ 
2: while  $i < k$  do
3:   Load the level- $i$  policy
4:   Set cognition levels of all players in the environ-
     ment other than the learning agent to level- $i$ , i.e.,
     set policies of players to level- $i$  policy
5:   Place the learning agent in the initialized environ-
     ment, in which all players are level- $i$ 
6:   Start the training of the learning agent using a rein-
     forcement learning method, through which agent
     learns how to best respond to level- $i$  players
7:   Once the training is completed, learning agent
     becomes a level- $(i+1)$  player
8:   Save the policy of the learning agent as level- $(i+1)$ 
     policy
9:    $i += 1$ 
10: end while

```

- (1) Suppose there are N consumption units capable of adjusting their loads located at a node in a power grid. This capability may be either due to the fact that the load itself is adjustable (e.g., temperature set-point in a HVAC system) or they include a storage unit that has a flexible charging/discharging schedule. The corresponding utility function of a unit k consists of $U(D_k, S_k)$, where D_k is the quantity of energy that is charged and S_k is the amount of energy discharged. In general U_k depends on the amount of energy imbalance, the price of electricity, the actions of other assets at that node and their flexibility, and the penalty that the power company may impose for unmet commitment, among others. The argument for using a PT-based model rather than EUT is because of the uncertainty introduced by other players in the underlying trading game. The effect of the overall risk-aversion may be modeled through the use of the (V, π) tuple described in (2) and (3) using (4) (Wang et al. 2014).
- (2) The second example has been explored in the context of ride-sharing services. Here, the utility function depends on both travel times and the price of the service and is of the form

$$U = X + b\gamma \quad (15)$$

where γ is the tariff from ride offer and is deterministic and b represents the weighting of the economic cost of the ride in comparison to the travel cost. The time-based utility is of the form

$$X = a_1 T_{\text{walk}} + a_2 T_{\text{wait}} + a_3 T_{\text{ride}} + c \quad (16)$$

and is a stochastic quantity, as each of the travel times can vary randomly. As the amount of stochasticity is significant, a prospect theory-based approach may be more appropriate. It should also be noted that the utility function is a continuous function, with the corresponding function $U(t)$ varying over an interval $[t_{\min}, t_{\max}]$ which is determined by the bounds of the overall travel. Each $U(t)$ has an associated cumulative distribution function $F(U)$. Since there is a significant subjective component in this problem, the passengers who are willing to accept the ride service may perceive the utility U as $V(U)$ and perceive the corresponding probability of $U(t)$ in a distorted manner as well. As the underlying utility function is continuous, one needs to adopt a CPT approach here (Tversky and Kahneman 1992).

We first present the CPT model for a discrete case, with utility U_i for outcome $i, i = 1, \dots, n$. Each U_i represents the utility of the ride-sharing service for a time cost t_i . For example, the wait time could be 10 min, the travel time 30 min, and the walk time 5 min, leading to a total time of 45 min, which has a certain utility to the passenger. The objective utility therefore can be calculated using (1). Using the CPT discussions above, the subjective utility can be calculated using (6). The extension from (6) to the continuous case of U_R^s then becomes

$$\begin{aligned}
U^s = & \int_{-\infty}^R V(u) \frac{d}{du} \left\{ \pi[F_U(u)] \right\} du \\
& + \int_R^{\infty} V(u) \frac{d}{du} \left\{ -\pi[1 - F_U(u)] \right\} du
\end{aligned} \quad (17)$$

One can similarly calculate the distorted probabilities. Suppose we consider a simple case each passenger is assumed to choose between two options, the ride-sharing service and another alternative such as public transportation, which may have a utility A^o . The objective probability of acceptance is given by

$$p^o = \frac{e^{U^o}}{e^{U^o} + e^{A^o}} \quad (18)$$

The subjective probability of acceptance is given by

$$p^s = \frac{e^{U^s}}{e^{U^s} + e^{A^s}} \quad (19)$$

where A^s denotes the subjective utility of the alternative perceived by the passenger. The overall prospect theory-based passenger model is then quantified using the pair (U^s, p^s) . These in turn could be used to determine the dynamic tariff of the ride-sharing service. Such an approach directly accommodates the behavioral model of humans. The reader is referred to Guan et al. (2019) for further details.

Shared Control Architectures

Shared control architectures (SCAs) exemplified in this section describe the responsibility sharing between pilots and autopilots in terms of controlling the aircraft. In section “Capacity for Maneuver Concept” two different models of human decision-making were discussed, both based on the monitoring of the CfM. In this section, we introduce two different SCAs based on these models (Eraslan et al. 2020).

SCA 1: A Pilot with a CfM-Based Perception and a Fixed-Gain Autopilot

The first shared control architecture can be summarized as a sequence {autopilot runs, anomaly occurs, pilot takes over}. That is, it is assumed that an autopilot based on PD control is in place, ensuring a satisfactory command tracking under nominal conditions. The human pilot is assumed to consist of a perception component and an adaptation component. The perception component consists of monitoring CfM, through which

a perception trigger F_0 is calculated using (8). The adaptation component consists of monitoring the control gain in (7) and taking over control of the aircraft when $K_t = 1$. The details of this shared controller and its evaluation using simulations and experiments are given by Farjadian et al. (2016) and Eraslan et al. (2020). Figure 1 illustrates the schematic of SCA1.

SCA 2: A Pilot with a CfM-Based Decision-Making and an Advanced Adaptive Autopilot

In this shared control architecture, the role of the pilot is a supervisory one, while the autopilot takes on an increased and complex role. The pilot is assumed to monitor the CfM of the actuators in the aircraft following an anomaly. In an effort to allow the CfM to stay close to a desired value, the command is allowed to be degraded; the pilot then determines a parameter μ which directly scales the control effort. Once μ is specified by the pilot, then the adaptive autopilot continues to supply the control input. If the pilot has high situational awareness, he/she provides an estimate of the severity of the anomaly. The details of this shared controller and its evaluation using simulations and experiments are given by Farjadian et al. (2017, 2020) and Eraslan et al. (2020). Figure 2 shows the schematic of SCA2.

Airspace in the Presence of Both Manned and Unmanned Aircraft

Obtaining airspace models where both manned and unmanned aircraft are present is a necessity for successful integration of unmanned aircraft systems (UAS) into the National Airspace System (NAS). Sense and avoid (SAA) algorithms, human-human and human-automation interactions through aircraft dynamics, aircraft, and traffic collision avoidance algorithms (TCAS), together with the communication links, make this system a typical example of a CPHS.

Figure 3 shows such an airspace scenario where a UAS (magenta) is assigned to follow certain waypoints (yellow) in a crowded airspace filled with manned aircraft (red). We are interested in how the overall system will evolve in time.

Cyber-Physical-Human Systems, Fig. 1 Block diagram of SCA1. (Adapted from Farjadian et al. 2016). The autopilot model consists of a fixed gain controller, whereas the human pilot model comprehends a perception part based on the CfM concept and an adaptation part governed by empirical adaptive laws (Hess 2016). The neuromuscular transfer function (Hess 2006), $G_{nm}(s)$,

corresponds to control input formed by an arm or leg. When an anomaly occurs, the plant dynamics, $Y_p(s)$, undergoes an abrupt change by rendering the autopilot insufficient for the rest of the control. At this stage, the occurrence of an anomaly is captured by the CfM such that the control is handed over to the human pilot model for a resilient flight control

To model this scenario, we need to include aircraft dynamics, TCAS and SAA algorithms, and communication dynamics which may include signal delays. These components of the model are already well understood and documented in the literature. The human interaction dynamics, on the other hand, is the main challenge.

As discussed in section “[Game Theory and Reinforcement Learning](#),” the GT- and RL-based modeling approach produces policies, which are probabilistic maps from observations to actions, to represent human interactions. Therefore, to obtain these policies, we first need to clearly define the *observation and action spaces* and represent them in a way that is meaningful for the RL algorithm. Once these spaces are explicitly defined, pilot goals and preferences need to be expressed in form of a *reward function*. Obtaining these policies and integrating them with the automation and the physical manned and unmanned aircraft dynamics enables a simulation capability to investigate and study various UAS integration into the NAS scenarios. A detailed

description of how to achieve this together with several simulation studies and validations with a data-based model is given by Musavi et al. (2016).

CPHS Beyond the Engineering Domain

The role of CPHS is significantly larger. Much of the focus in the topics outlined above was on engineering systems and how we come up with better tools for their analysis and synthesis. The focus needs to be diverted towards social systems as well and how the emergence of CPHS and the varied roles of humans therein introduce new challenges therein, in domains related to ethics, economics, justice, and the like. While the topic of ethics has been studied for millennia by societies and civilizations, the creation of new socio-technical systems introduces new paradigms for societal interactions and thereby new challenges.

Cyber-Physical-Human Systems, Fig. 2 Block diagram of SCA 2. The human pilot undertakes a supervisory role by providing the key parameters μ and $\hat{\lambda}_{fp}$ to the

adaptive autopilot. The blocks are expressed in different colors based on their functions in the proposed SCA2

This entry would not be complete without bringing in yet another important connection between systems and control and social sciences, which can be grouped under the rubric of dynamics over techno-social networks, DTSN (see Section 5.20 on Social Networks in Lamnabhi-Lagarrigue et al. (2017)). DTSN has its origins in social network analysis which is grounded in social philosophy and psychology and focuses on the examination of social relations, influences, group actions, and interactions. By leveraging the intersection between SNA and graph theory, several computationally efficient algorithms have been derived for the analysis of large-scale systems. With rapid changes in technology, these large-scale systems are now beginning to have a strong temporal signature, which implies the need for a dynamical system point of view, leading to DTSN. The focus of this emerging area has a huge range of applicability, with its emphasis on the study of both topological and dynamical

properties of the network, properties of resilience and robustness in the presence of natural disasters and cyberattacks that may cause failures in nodes and links in the network. A notable and topical application area is the current COVID-19 spread over the world population.

Summary

As societal challenges increase, there is an increasing need for human systems to interact with cyber-physical systems in various ways to provide innovative solutions that overcome these challenges. The rubric that addresses the foundations of such emerging interactions and integrations between CPS and human systems forms CPHS. This entry provides an introduction to CPHS and representative examples from energy and transportation sectors where such CPHS have begun to emerge.

Cyber-Physical-Human Systems, Fig. 3 A hybrid airspace scenario where red squares represent manned aircraft and the magenta square is used to indicate an unmanned aircraft (UA). The yellow circles in the 600 ×

300 km airspace are the waypoints assigned to the UA. (Musavi et al. (2016), reprinted by permission of the American Institute of Aeronautics and Astronautics, Inc)

One of the main challenges in CPHS is modeling of the human element. Given the enormously complex human system that functions over a huge range of timescales to perform a wide range of tasks, there are perhaps as many models of humans needed for as many problems. The models presented in this entry therefore are in no way meant to be comprehensive but rather illustrations. We have focused on a few instances where the underlying models attempt to capture the perceptive, strategic, and decision-making abilities of humans in various contexts. In addition, we have tried to illustrate varied concepts and methodologies which include prospect theory, game theory and reinforcement learning, and capacity for maneuver that may be appropriate for deriving human models in these contexts.

While the applications that we have outlined in this entry correspond to the energy and transportation sectors, by no means are they meant to be the only applications of interest in CPHS. Several examples abound in the area of robotics,

healthcare, and manufacturing, which have not been covered here (see the ongoing IFAC workshop series on CPHS for ongoing and emerging activities in this area!).

Data Association

Yaakov Bar-Shalom and Richard W. Osborne
University of Connecticut, Storrs, CT, USA

Abstract

In tracking applications, following the signal detection process that yields measurements, there is a procedure that *selects* the measurement(s) to be incorporated into the state estimator – this is called **data association (DA)**. In multitarget-multisensor tracking systems, there are generally three classes of data association: specifically, **measurement-to-track association (M2TA)**, **track-to-track association (T2TA)**, and **measurement-to-measurement association (M2MA)**. M2TA is the process of associating each measurement from a list (originating from one or more sensors) to a new or existing track. T2TA is the process of associating multiple existing tracks (from multiple sensors or from different periods in time), generally with the intent of fusing them afterward. M2MA is the process of associating measurements from different sensors in order to form “composite measurements” and/or do track initialization. The processes of M2TA and T2TA will be discussed in more detail here, while details on M2MA can be found in Bar-Shalom et al. (2011).

Keywords

Clutter · Measurement origin uncertainty · Measurement validation · Persistent interference · Tracking

Introduction

In a radar the “return” from the target of interest is sought within a time interval determined by the anticipated range of the target when it reflects the energy transmitted by the radar: a “range gate” is set up and the detection(s) within this gate can be *associated* with the target of interest.

In general the measurements have a higher dimension:

- Range, azimuth (bearing), elevation, or direction sines for radar, possibly also range rate
- Bearing and frequency (when the signal is narrow band) or time difference of arrival and frequency difference in passive sonar
- Two line-of-sight angles or direction sines for optical or passive electromagnetic sensors

Then a *multidimensional gate* is set up for detecting the signal from the target. This is done to avoid searching for the signal from the target of interest in the entire measurement space. A measurement in the gate, while not guaranteed to have originated from the target the gate pertains to, is a *valid association candidate* – thus, the name **validation region** or **association region**. If there

is more than one detection (measurement) in the gate, this leads to an **association uncertainty**.

In the discussion to follow, it will be assumed that one has **point measurements** rather than distributed over several **resolution cells** of the sensor as in the case of an **extended target**.

Similar validation has to be carried out in T2TA.

Validation Region

In view of the variety of variables that can be measured, a generic gating (or validation or association) procedure for continuous-valued measurements is discussed.

Consider a target that is in track, i.e., its filter has been initialized. Then, according to Sect. 5.2.3 of Bar-Shalom et al. (2001), one has the predicted value (mean) of the measurement $\hat{z}(k+1|k)$ and the associated covariance $S(k+1)$.

Assumption. The true measurement conditioned on the past is **normally (Gaussian) distributed** (The notation $\mathcal{N}(x; \mu, S)$ stands for the normal (Gaussian) pdf with the argument (vector) random variable x , mean μ , and covariance matrix S . The reason for the use of the designation “normal” is to distinguish this omnipresent pdf from all the others (abnormal).) with its **probability density function (pdf)** given by

$$p[z(k+1)|Z^k] = \mathcal{N}[z(k+1); \hat{z}(k+1|k), S(k+1)] \quad (1)$$

where $S(k+1)$ is the **innovation (residual) covariance** matrix and z is the true measurement.

Then the true measurement will be in the following region:

$$\mathcal{V}(k+1, \gamma) = \{z : d^2 \leq \gamma\} \quad (2)$$

with probability determined by the **gate threshold** γ and

$$d^2 \triangleq [z - \hat{z}(k+1|k)]' S(k+1)^{-1} [z - \hat{z}(k+1|k)] \quad (3)$$

This distance metric, d^2 , is referred to in the literature as the **normalized innovation squared (NIS)**, **statistical distance squared**, **Mahalanobis distance**, or **chi-square distance**.

The region defined by (2) is called the **gate** or **validation region** (hence, the notation $\mathcal{V}$) or **association region**. It is also known as the **ellipsoid (or ellipsoid) of probability concentration** – the region of *minimum volume* that contains a given probability mass under the Gaussian assumption. The semiaxes of the ellipsoid (2) are the square roots of the eigenvalues of γS . The threshold γ is obtained from tables of the chi-square distribution since the quadratic form (3) that defines the validation region in (2) is chi-square distributed with number of degrees of freedom equal to the dimension n_z of the measurement.

Table 1 gives the **gate probability** (The notation $P\{\cdot\}$ is used to denote the probability of event $\{\cdot\}$.)

$$P_G \triangleq P\{z(k+1) \in \mathcal{V}(k+1, \gamma)\} \quad (4)$$

or the “probability that the (true) measurement will fall in the gate” for various values γ and dimensions n_z of the measurement. The square root $g = \sqrt{\gamma}$ is sometimes referred to as the “number of sigmas” (standard deviations) of the gate. This, however, does not fully define the probability mass in the gate as can be seen from Table 1.

Remark 1 It should be pointed out that thresholding in a detector is also a form of gating – only a signal above a certain intensity level (at the end of the signal processing chain) is accepted as a detection and then one has a measurement. In this case the “gate” is the interval $[\tau, \infty]$ in the signal intensity space, where τ is the detection threshold.

A Single Target in Clutter

The validation procedure limits the region in the measurement space where the information processor will “look” to find the measurement from the target of interest. In spite of this, it can happen that *more than one detection*, i.e., several

Data Association, Table 1 Gate thresholds and the probability mass P_G in the gate

γ	1	4	6.6	9	9.2	11.4	16	25
g	1	2	2.57	3	3.03	3.38	4	5
n_z								
1	0.683	0.954	0.99	0.997			0.99994	1
2	0.393	0.865		0.989	0.99		0.9997	1
3	0.199	0.739		0.971		0.99	0.9989	0.99998

measurements, will be found in the validation region.

Measurements *outside the validation region* can be ignored: they are “too far” and thus very unlikely to have originated from the target of interest. This holds if the gate probability is close to unity and *the model used to obtain the gate is correct*.

The problem of tracking a single target in clutter considers the situation where there are possibly several measurements in the validation region (gate) of a target. The set of **validated measurements** consists of:

- The correct measurement (if detected and it fell in the gate)
- The undesirable measurements: clutter or false alarm originated

In practice detections are obtained by thresholding the signal received by the sensor after processing it. This is the simplest (binary) way of using a target **feature** – its intensity. More sophisticated ways of using such feature information can be found in Bar-Shalom et al. (2011).

It is assumed that the measurement contains all the information that could be used to discard the undesirable measurements. Therefore, any measurement that has been validated could have originated from the target of interest.

A situation with a single-target track and several validated measurements is depicted in Fig. 1. The (two-dimensional) validation region is an ellipse centered at the predicted measurement $\hat{z}^1$. The parameters of the ellipse are determined by the covariance matrix S of the innovation, which is assumed to be Gaussian.

**Data Association, Fig. 1** Several measurements in the validation region of a single track

All the measurements in the validation region can be said to be *not too unlikely* to have originated from the target of interest, even though only one is assumed to be the true one.

The implication of the assumption that there is a single target is that the *undesirable measurements constitute a random interference*. The common mathematical model for such **false measurements** is that they are:

- Uniformly spatially distributed
- Independent across time

This corresponds to what is known as **residual clutter** – the constant clutter, if any, is assumed to have been removed.

Multiple Targets in Clutter

The situation where there are several target tracks in the same neighborhood as well as clutter (or false alarms) is more complicated. Figure 2 illustrates such a case for a given time, with the predicted measurements for the two targets considered denoted as $\hat{z}^1$ and $\hat{z}^2$. In this figure the following measurement origins are possible:

Data Association, Fig. 2 Two tracks with a measurement in the intersection of their validation regions

- z_1 from target 1 or clutter
- z_2 from either target 1 or target 2 or clutter
- z_3 and z_4 from target 2 or clutter

However, if z_2 originated from target 2, then it is quite likely that z_1 originated from target 1. This illustrates the *interdependence of the associations* in a situation where a **persistent interference** (neighboring target) is present in addition to random interference (clutter).

Up to this point, it was assumed that a measurement could have originated from *one of the targets* or from *clutter*. However, in view of the fact that any signal processing system has an inherent **finite resolution** capability, an additional possibility has to be considered:

z_2 could be the result of the **merging** of the detections from the two targets – it is an **unresolved measurement**.

This constitutes a fourth origin hypothesis for a measurement that lies in the intersection of two validation regions. Most tracking algorithms ignore the possibility that a measurement is an unresolved one.

This illustrates only the difficulty of association of measurements to tracks *at one point in time*. The full problem, as will be discussed later, consists of associating measurements *across time*.

Approaches to Tracking and Data Association

The problem of **tracking and data association** is a **hybrid** problem because it is characterized by:

- (1) Continuous uncertainties – state estimation in the presence of continuous noises
- (2) Discrete uncertainties – which measurement(s) should be used in the estimation process

Assuming the goal is to obtain the MMSE estimate of the target state – its conditional mean – one can distinguish the following approaches.

Pure MMSE Approach

The **Pure MMSE Approach** to tracking and data association is obtained using the smoothing property of expectations (see, e.g., Bar-Shalom et al. 2001, Sect. 1.4.12), as follows:

$$\begin{aligned}\hat{x}^{\text{MMSE}} &= E[x|Z] = E\{E[x|A, Z]|Z\} \\ &= \sum_{A_i \in \mathcal{A}} E[x|A_i, Z] P\{A_i|Z\}\end{aligned}\quad (5)$$

where A is an association event (assuming a Bayesian model, with prior probabilities from which one can calculate posterior probabilities), and the summation is over all events A_i in the set $\mathcal{A}$ of mutually exclusive and exhaustive association events.

The above, which requires the evaluation of all the conditional (posterior) probabilities $P\{A_i|Z\}$, is a direct consequence of the **total probability theorem** (see, e.g., Bar-Shalom et al. 2001, Sect. 1.4.10), which yields the conditional pdf of the state as the following mixture

$$p(x|Z) = \sum_{A_i \in \mathcal{A}} p(x|A_i, Z) P\{A_i|Z\} \quad (6)$$

In the linear-Gaussian case the above becomes a **Gaussian mixture**. Algorithms that fall in this category are PDAF and JPDAF, see Bar-Shalom et al. (2011).

MMSE-MAP Approach

The **MMSE-MAP Approach**, instead of enumerating and summing over all the association events, selects the one with highest posterior probability, namely,

$$A^{\text{MAP}} = \arg \max_i P\{A_i|Z\} \quad (7)$$

and then

$$\hat{x}^{\text{MMSE-MAP}} = E[x|A^{\text{MAP}}, Z] \quad (8)$$

The HOMHT as proposed by Reid (1979) falls in this category, see Bar-Shalom et al. (2011).

MMSE-ML Approach

The **MMSE-ML Approach** does not assume priors for the association events and relies on the maximum likelihood approach to select the event, that is,

$$A^{\text{ML}} = \arg \max_i p\{Z|A_i\} \quad (9)$$

and then

$$\hat{x}^{\text{MMSE-ML}} = E[x|A^{\text{ML}}, Z] \quad (10)$$

The TOMHT falls into this category and S-D assignment (or MDA) is an implementation of this, see Bar-Shalom et al. (2011).

Heuristic Approaches

There are numerous simpler/heuristic approaches. The most common one relies on the distance metric (3) and makes the selection of which measurement is associated with which track based on the “nearest neighbor” rule. The same criterion can be used in a global cost function.

Remarks

It should be noted that the MMSE-MAP estimate (8) and the MMSE-ML estimate (10) are obtained assuming that the selected association is *correct* – a **hard decision**. This hard decision is sometimes correct, sometimes wrong. On the other hand, the pure MMSE estimate (5) yields a **soft decision** – it averages over all the possibilities. This soft decision is never totally correct, never totally wrong.

The uncertainties (covariances) associated with the MMSE-MAP and MMSE-ML estimates might be optimistic in view of the above observation. The uncertainty associated with the pure MMSE estimate will be *increased* (realistically) in view of the fact that it includes the data association uncertainty.

Estimation and Data Association in Nonlinear Stochastic Systems

The Model

Consider the discrete time stochastic system

$$\mathbf{x}(k+1) = f[k, \mathbf{x}(k), \mathbf{u}(k), \mathbf{v}(k)] \quad (11)$$

where $\mathbf{x} \in \mathcal{R}^n$ is the stacked state vector of the targets under consideration, $\mathbf{u}(k)$ is a known input (included here for the sake of generality), and $\mathbf{v}(k)$ is the process noise with a known pdf. The measurements at time $k+1$ are described by the stacked vector

$$\mathbf{z}(k+1) = h[k+1, \mathbf{x}(k+1), A(k+1), \mathbf{w}(k+1)] \quad (12)$$

where $A(k+1)$ is the data association event at $k+1$ that specifies (i) which measurement component originated from which components of $\mathbf{x}(k+1)$, namely, from which target, and (ii) which measurements are false, that is, originated from the clutter process. The vector $\mathbf{w}(k)$ is the observation noise, consisting of the error in the true measurement and the false measurements. The pdf of the false measurements and the probability mass function (pmf) of their number are also assumed to be known.

The noise sequences and false measurements are assumed to be white with known pdf and mutually independent. The initial state is assumed to have a known pdf and to be independent of the noises. Additional assumptions are given below for the optimal estimator, which evaluates the pdf of the state conditioned on the observations.

The optimal state estimator in the presence of data association uncertainty consists of the computation of the conditional pdf of the state $\mathbf{x}(k)$ given all the information available at time k , namely, the prior information about the initial state, the intervening inputs, and the sets of measurements through time k . The conditions under which the optimal state estimator consists of the computation of this pdf are presented in detail.

The Optimal Estimator for the Pure MMSE Approach

The **information set** available at k is

$$I^k = \{Z^k, U^{k-1}\} \quad (13)$$

where

$$Z^k \triangleq \{\mathbf{z}(j)\}_{j=1}^k \quad (14)$$

is the cumulative set of observations through time k , which subsumes the initial information Z^0 , and U^{k-1} is the set of known inputs prior to time k .

For a stochastic system, an **information state** (Striebel 1965) is a function of the available information set that summarizes the past of the system in a probabilistic sense.

It can be shown that the conditional pdf of the state

$$p_k \triangleq p[\mathbf{x}(k)|I^k] \quad (15)$$

is an information state if (i) the two noise sequences (process and measurement) are white and mutually independent and (ii) the target detection and clutter/false measurement processes are white. Once the conditional pdf (15) is available, the **pure MMSE estimator**, i.e., the conditional mean, as well as the conditional variance, or covariance matrix, can be obtained.

The optimal estimator, which consists of the recursive functional relationship between the

information states p_{k+1} and p_k , is given by

$$p_{k+1} = \psi[k+1, p_k, \mathbf{z}(k+1), \mathbf{u}(k)] \quad (16)$$

where

$$\begin{aligned} & \psi[k+1, p_k, \mathbf{z}(k+1), \mathbf{u}(k)] \\ &= \frac{1}{c} \sum_{i=1}^{M(k+1)} p[\mathbf{z}(k+1)|\mathbf{x}(k+1), A_i(k+1)] \\ & \cdot \int p[\mathbf{x}(k+1)|\mathbf{x}(k), \mathbf{u}(k)] p_k d\mathbf{x}(k) \\ & P\{A_i(k+1)\} \end{aligned} \quad (17)$$

is the transformation that maps p_k into p_{k+1} ; the integration in (17) is over the range of $\mathbf{x}(k)$ and c is the normalization constant.

The recursion (17) shows that the optimal MMSE estimator in the presence of data association uncertainty has the following properties:

- P1. The pdf p_{k+1} is a weighted sum of pdfs, conditioned on the current time association events $A_i(k+1)$, $i = 1, \dots, M(k+1)$, where $M(k+1)$ is the number of mutually exclusive and exhaustive association events at time $k+1$.
- P2. If the exact previous pdf, which is the sufficient statistic, is available, then only the most recent association event probabilities are needed at each time.

However, the number of terms of the mixture in the right-hand side of (17) is, by time $k+1$, given by the product

$$M^{k+1} = \prod_{i=1}^{k+1} M(i) \quad (18)$$

which amounts to an exponential increase in time. This increase is similar to the increase in the number of the branches of the MHT hypothesis tree.

A detailed derivation of the recursion for the optimal estimator can be found in Bar-Shalom et al. (2011).

Track-to-Track Association

In addition to **measurement-to-track association (M2TA)**, an additional class of data association is **track-to-track association (T2TA)**. Following T2TA, **track-to-track fusion (T2TF)** may be performed to (hopefully) improve the overall tracking accuracy. For more details on track fusion, see Bar-Shalom et al. (2011).

It is desired first to test the hypothesis that two tracks pertain to the same target. The optimal test would require using the entire data base (the sequences of measurements that form the tracks) through the present time k and is not practical. In view of this, the test to be presented is based only on the most recent estimates from the tracks. The test based on the state estimates within a time window is discussed in Tian and Bar-Shalom (2009).

Association of Tracks with Independent Errors

Let $\hat{x}^i(k)$ be the estimated state of a target by sensor i with its own information processor. Assume that one has an estimate $\hat{x}^j(k)$ from sensor j , corresponding to the same time. Both can be current estimates or one can be a prediction as long as they pertain to the same time (the second time argument has been omitted for simplicity).

The corresponding covariances are denoted as $P^m(k)$, $m = i, j$. The state estimation errors at different sensors (local trackers),

$$\tilde{x}^i(k) = x^i(k) - \hat{x}^i(k) \quad (19)$$

$$\tilde{x}^j(k) = x^j(k) - \hat{x}^j(k) \quad (20)$$

where x^i and x^j are the corresponding true states, are assumed to be *independent*. This is the **state estimation error independence assumption**.

Remark 2 As shown in the sequel, for *independent sensors*, the state estimation errors for the same target are *dependent* in the *presence of process noise*.

Denote the difference of the two estimates as

$$\hat{\Delta}^{ij}(k) = \hat{x}^i(k) - \hat{x}^j(k) \quad (21)$$

This is the estimate of the difference of the true states

$$\Delta^{ij}(k) = x^i(k) - x^j(k) \quad (22)$$

The **same target hypothesis** is that the true states are equal,

$$H_0 : \quad \Delta^{ij}(k) = 0 \quad (23)$$

while the *different target* alternative is

$$H_1 : \quad \Delta^{ij}(k) \neq 0 \quad (24)$$

While (21) is the appropriate statistic to test whether (22) is zero or not, the rigorous proof of this fact is presented in Bar-Shalom et al. (2011).

The error in the difference between the state estimates

$$\tilde{\Delta}^{ij}(k) = \Delta^{ij}(k) - \hat{\Delta}^{ij}(k) \quad (25)$$

is zero mean and has covariance

$$\begin{aligned} T^{ij}(k) &\triangleq E\{\tilde{\Delta}^{ij}(k)\tilde{\Delta}^{ij}(k)'\} \\ &= E\{[\tilde{x}^i(k) - \tilde{x}^j(k)][\tilde{x}^i(k) - \tilde{x}^j(k)]'\} \end{aligned} \quad (26)$$

given, under the **error independence assumption**, by

$$T^{ij}(k) = P^i(k) + P^j(k) \quad (27)$$

Assuming the estimation errors to be Gaussian, the test of H_0 vs. H_1 – the **T2TA** test – is

Accept H_0 if

$$D \triangleq \hat{\Delta}^{ij}(k)'[T^{ij}(k)]^{-1}\hat{\Delta}^{ij}(k) \leq D_\alpha \quad (28)$$

The threshold D_α is such that

$$P\{D > D_\alpha | H_0\} = \alpha \quad (29)$$

where, e.g., $\alpha = 0.01$. From the Gaussian assumption, the threshold is the $1 - \alpha$ point of the **chi-square distribution** with n_z degrees of freedom (Bar-Shalom et al. 2001)

$$D_\alpha = \chi_{n_z}^2(1 - \alpha) \quad (30)$$

Association of Tracks with Dependent Errors

In the previous section, the association testing was done under the assumption that the estimation errors in these tracks are independent. However, as shown in Bar-Shalom et al. (2011), *whenever there is process noise* (or, in general, motion uncertainty), the track errors based on data from *independent sensors are dependent*.

The *dependence* between the estimation errors $\tilde{x}^i(k|k)$ and $\tilde{x}^j(k|k)$ from the two tracks arises from the *common process noise* which contributes to both errors. This is due to the fact that there is a common motion equation for both trackers.

The testing of the hypothesis that the two tracks under consideration originated from the same target is done in the same manner as before, except for the following modification to account for the *dependence* of their state estimation errors.

The covariance associated with the difference of the estimates

$$\hat{\Delta}^{ij}(k) = \hat{x}^i(k|k) - \hat{x}^j(k|k) \quad (31)$$

is, accounting for the dependence,

$$\begin{aligned} T^{ij}(k) &\triangleq E\{\tilde{\Delta}^{ij}(k)\tilde{\Delta}^{ij}(k)'\} \\ &= E\{[\tilde{x}^i(k|k) - \tilde{x}^j(k|k)][\tilde{x}^i(k|k) \\ &\quad - \tilde{x}^j(k|k)]'\} \end{aligned} \quad (32)$$

and, with the known cross-covariance P^{ij} , is given by the expression

$$\begin{aligned} T^{ij}(k) &= P^i(k|k) + P^j(k|k) \\ &\quad - P^{ij}(k|k) - P^{ji}(k|k) \end{aligned} \quad (33)$$

Note the difference between the above and (27).

Effect of the Dependence

The effect of the dependence between the estimation errors is to *reduce* the covariance of the difference (31) of the estimates. This is due to

the fact that the cross-covariance term reflects a positive correlation between the estimation errors (this is always the case for linear systems).

The Test

The hypothesis testing for the **track-to-track association** with the dependence accounted for is done in the same manner as before in (28), except that the “smaller” covariance from (33) is used in the test statistic, which is, as before, the **normalized distance squared** between the estimates

$$D = \hat{\Delta}^{ij}(k)'[T^{ij}(k)]^{-1}\hat{\Delta}^{ij}(k) \quad (34)$$

The Cross-Covariance of the Estimation Errors

The **cross-covariance recursion** for *synchronized sensors* can be shown to be (see Bar-Shalom et al. 2011)

$$\begin{aligned} P^{ij}(k|k) &\triangleq E[\tilde{x}^i(k|k)\tilde{x}^j(k|k)'] \\ &= [I - W^i(k)H^i(k)] \\ &\quad \cdot \left[F(k-1)P^{ij}(k-1|k-1)F(k-1)' \right. \\ &\quad \left. + Q(k-1) \right] [I - W^j(k)H^j(k)]' \end{aligned} \quad (35)$$

This is a *linear recursion* – a Lyapunov-type equation – and its initial condition is, assuming the initial errors to be uncorrelated,

$$P^{ij}(0|0) = 0 \quad (36)$$

This is a reasonable assumption in view of the fact that the initial estimates are usually based on the initial measurements, which were assumed to have independent errors.

The cross-covariance for the case of asynchronous sensors can be found in Bar-Shalom et al. (2011).

Summary and Future Directions

This entry surveyed the issues involved in data association (specifically M2TA and T2TA) with regard to multitarget-multisensor tracking systems.

The future developments in this topic will be in regard to the use of new feature variables and classification in data association (some preliminary results are in Bar-Shalom et al. (2011)).

Data Rate of Nonlinear Control Systems and Feedback Entropy

Christoph Kawan
Courant Institute of Mathematical Sciences,
New York University, New York, USA

Abstract

Topological feedback entropy is a measure for the smallest information rate in a digital

communication channel between the coder and the controller of a control system, above which the control task of rendering a subset of the state space invariant can be solved. It is defined purely in terms of the open-loop system without making reference to a particular coding and control scheme and can also be regarded as a measure for the inherent rate at which the system generates “invariance information.”

Keywords

Communication constraints · Controlled invariance · Invariance entropy · Minimal data rates · Stabilization

Introduction

In the theory of networked control systems, the assumption of classical control theory that information can be transmitted within control loops instantaneously, lossless, and with arbitrary precision is no longer satisfied. Realistic mathematical models of many important real-world communication and control networks have to take into account general data rate constraints in the communication channels, time delays, partial loss of information, and variable network topologies. This raises the question about the smallest possible information rate above which a given control task can be solved. Though networked control systems can have a complicated topology, consisting of multiple sensors, controllers, and actuators, a first step towards understanding the problem of minimal data rates is to analyze the simplest possible network topology, consisting of one controller and one dynamical system connected by a digital channel with a certain rate in bits per unit time. There is a wealth of literature concerned with the problem of stabilizing a system under different assumptions about the specific coding and control scheme, in this context. However, with few exceptions, mainly linear systems (both deterministic and stochastic) have been considered. A comprehensive and detailed overview of this literature until 2007 can be found in the survey Nair et al. (2007). The first

systematic approach to the problem of minimal data rates for set invariance and stabilization of (deterministic, nonlinear) control systems was presented in Nair et al. (2004), where the notion of *topological feedback entropy* was introduced. This quantity, defined in terms of the open-loop control system, is a measure for the smallest data rate a communication channel may have if the system is supposed to solve the control task of rendering a subset of the state space invariant. Other challenges that digital communication channels come along with are not yet taken into account here.

Feedback entropy was first introduced in Nair et al. (2004), using a similar approach via open covers as in the definition of topological entropy of for classical dynamical systems in Adler et al. (1965). In Colonius and Kawan (2009), a quantity named *invariance entropy* was defined which later turned out to be equivalent to the feedback entropy of Nair et al. (cf. Colonius et al. 2013). The notion of invariance entropy has been further studied in the papers Kawan (2011a), Kawan (2011b), and Kawan (2011c). Several variations and generalizations have been introduced in Colonius (2010), Colonius (2012), Colonius and Kawan (2011), Da Silva (2013), and Hagihara and Nair (2013). The research monograph Kawan (2013) provides a comprehensive presentation of the results obtained so far in the deterministic case.

Definition

Topological feedback entropy is a nonnegative real-valued quantity which serves as a measure for the smallest possible data rate in a digital channel, connecting a coder to a controller, above which the controller is able to generate inputs which guarantee invariance of a given subset of the state space. In the literature, one finds several slightly differing versions. The original definition given in Nair et al. (2004) is (with minor modifications) as follows. Consider a discrete-time control system

$$x_{k+1} = F(x_k, u_k) = F_{u_k}(x_k), \quad k \geq 0,$$

with $F : X \times U \rightarrow X$, where X is a topological space and U a nonempty set such that $F_u : X \rightarrow X$ is continuous for every $u \in U$. The transition map associated to this system is

$$\begin{aligned} \varphi : \mathbb{N}_0 \times X \times U^{\mathbb{N}_0} &\rightarrow X, \\ \varphi(k, x, (u_n)) &:= F_{u_{k-1}} \circ \cdots \circ F_{u_1} \circ F_{u_0}(x). \end{aligned}$$

A compact subset $K \subset X$ with nonempty interior is (*strongly*) *controlled invariant* if for every $x \in K$ there is an input $u \in U$ such that $F_u(x) \in \text{int}K$. A triple $(\mathcal{A}, \tau, G)$ is called an *invariant open cover* of K if $\mathcal{A}$ is an open cover of K , τ is a positive integer, and $G : \mathcal{A} \rightarrow U^\tau$ is a map with components $G_0, G_1, \dots, G_{\tau-1}$ which assign control values to all sets in $\mathcal{A}$ such that for every $A \in \mathcal{A}$ the finite sequence of controls $G(A)$ yields $\varphi(k, A, G(A)) \subset \text{int}K$ for $k = 1, 2, \dots, \tau$. The *entropy* of $(\mathcal{A}, \tau, G)$ is defined as follows. For every sequence $\alpha = (A_i)_{i \geq 0}$ of sets in $\mathcal{A}$ one defines an associated sequence of controls by

$$\begin{aligned} \underline{u}(\alpha) &= (u_0, u_1, u_2, \dots) \quad \text{with } (u_l)_{l=(i-1)\tau}^{i\tau-1} \\ &= G(A_{i-1}) \quad \text{for all } i \geq 0, \end{aligned}$$

and for every $j \geq 1$ a set

$$\begin{aligned} B_j(\alpha) &:= \{x \in X : \varphi(i\tau, x, \underline{u}(\alpha)) \in A_i \\ &\quad \text{for } i = 0, 1, \dots, j-1\}. \end{aligned}$$

The family $\mathcal{B}_j := \{B_j(\alpha) : \alpha \in \mathcal{A}^{\mathbb{N}_0}\}$ is an open cover of K . Letting $N(\mathcal{B}_j|K)$ denote the minimal cardinality of a finite subcover, the entropy of $(\mathcal{A}, \tau, G)$ is

$$\begin{aligned} h(\mathcal{A}, \tau, G) &:= \lim_{j \rightarrow \infty} \frac{1}{j\tau} \log_2 N(\mathcal{B}_j|K) \\ &= \inf_{j \geq 1} \frac{1}{j\tau} \log_2 N(\mathcal{B}_j|K). \end{aligned}$$

Finally, the topological feedback entropy (TFE) of K is given by

$$h_{\text{fb}}(K) := \inf_{(\mathcal{A}, \tau, G)} h(\mathcal{A}, \tau, G),$$

where the infimum is taken over all invariant open covers of K .

A conceptually simpler but equivalent definition, introduced in Colonius and Kawan (2009), is the following. A subset $\mathcal{S} \subset U^\tau$ is called (τ, K) -spanning if for every $x \in K$ there is $\underline{u} \in \mathcal{S}$ with $\varphi(k, x, \underline{u}) \in \text{int}K$ for $k = 1, \dots, \tau$. Writing $r_{\text{inv}}(\tau, K)$ for the minimal cardinality of such a set, it can be shown that

$$\begin{aligned} h_{\text{fb}}(K) &= \lim_{\tau \rightarrow \infty} \frac{1}{\tau} \log_2 r_{\text{inv}}(\tau, K) \\ &= \inf_{\tau \geq 1} \frac{1}{\tau} \log_2 r_{\text{inv}}(\tau, K). \end{aligned}$$

This definition and several variations of it are mostly referred to by the name *invariance entropy* instead of feedback entropy. The intuition behind this definition is that a controller which receives a certain amount of information about the state, say n bits, can generate at most 2^n different control sequences to steer the system on a finite time interval and hence, the number of control sequences needed to accomplish the control task on this interval is a measure for the necessary amount of information.

The different variations of feedback or invariance entropy which can be found in the literature are briefly summarized as follows. For simplicity, in this entry we refer to several of these variations by the name *(topological) feedback entropy*:

- (i) Instead of requiring that trajectories enter the interior of K after one step of time, one can allow for a waiting time τ_0 before entering $\text{int}K$.
- (ii) One can require that trajectories stay in K instead of $\text{int}K$ or that they stay in an arbitrarily small neighborhood of K , respectively.
- (iii) One can restrict the set of initial states to a subset of $K' \subset K$. In this case, a set $\mathcal{S}$ of control sequences is (τ, K', K) -spanning if for every $x \in K'$ there is $\underline{u} \in \mathcal{S}$ with $\varphi(k, x, \underline{u}) \in \text{int}K$ for $k = 1, \dots, \tau$.
- (iv) Feedback entropy can be defined for other classes of systems, e.g., continuous-time

deterministic systems, random control systems, or systems with piecewise continuous right-hand sides.

There is also a local version of topological feedback entropy (LTFE) which measures the smallest data rate for local uniform asymptotic stabilization at an equilibrium. Also for other control tasks there have been attempts to define corresponding versions of feedback or invariance entropy.

Comparison to Topological Entropy

Though there are similarities in the definitions of TFE and topological entropy of dynamical systems, which also reflect in similar properties, there is no direct relation between these two quantities. Topological entropy detects exponential complexity in the orbit structure of a dynamical system. In contrast, TFE measures the complexity of the control task to keep a system in a subset of the state space by applying appropriate inputs. If no escape from this subset is possible, the TFE is zero, no matter how complicated the orbit structure is. Hence, topological entropy is sensitive to the local behavior of the system, while TFE in general is not. Interpreted in terms of information rates, topological entropy is a measure for the largest average rate of information about the initial state a dynamical system can generate. TFE measures the smallest rate of information about the state of the system above which a controller is able to render the set invariant. It should also be mentioned that topological entropy was first introduced as a topological counterpart of the measure-theoretic entropy defined by Kolmogorov and Sinai, and that the two notions are related by the variational principle, which asserts that the topological entropy is the supremum of the measure-theoretic entropies with respect to all invariant probability measures of the given system. For TFE, so far no convincing measure-theoretic approach exists. An excellent survey on the entropy theory of dynamical systems can be found in Katok (2007).

The Data Rate Theorem

The *data rate theorem* for the TFE confirms that the infimal data rate in a coding and control loop which guarantees strong controlled invariance of a set K is equal to $h_{\text{fb}}(K)$. More precisely, suppose that a sensor which measures the state of the system at discrete times $\tau_k = k\tau$, $k = 0, 1, 2, \dots$, is connected to a coder which at time τ_k has a finite alphabet S_k of symbols available. The measured state is coded by use of this alphabet and the corresponding symbol is sent via a noiseless digital channel to a controller which generates an input sequence of length τ . This sequence is used to steer the system until the next symbol arrives at time τ_{k+1} . The associated *asymptotic average bit rate*, which depends on the sequence $S = (S_k)_{k \geq 0}$ of coding alphabets, is given by

$$R(S) = \lim_{k \rightarrow \infty} \frac{1}{k\tau} \sum_{i=0}^{k-1} \log_2 |S_i|.$$

If the limit does not exist, one may replace it with $\liminf$ or $\limsup$. The data rate theorem establishes the equality

$$h_{\text{fb}}(K) = \inf_S R(S),$$

where the infimum is taken over all coding and control loops which guarantee strong controlled invariance of K , i.e., for initial states in K they generate trajectories $(x_k)_{k \geq 0}$ with $x_k \in \text{int}K$ for $k = 1, 2, \dots$. Similar data rate theorems can be proved for other variants of feedback entropy. In particular, the data rate theorem for the LTFE asserts that the infimal bit rate for local uniform asymptotic stabilization at an equilibrium is given by the LTFE. Proofs of different data rate theorems can be found in Nair et al. (2004), Hagihara and Nair (2013), and Kawan (2013).

Estimates and Formulas

Linear Systems

For linear systems, under reasonable assumptions, the feedback entropy is given by the sum of

the unstable eigenvalues of the dynamical matrix, i.e., if the system is given by $x_{k+1} = Ax_k + Bu_k$, then

$$h_{\text{fb}}(K) = \sum_{\lambda \in \text{Sp}(A)} \max \{0, n_\lambda \log_2 |\lambda|\}, \quad (1)$$

where $\text{Sp}(A)$ denotes the spectrum of A and n_λ is the algebraic multiplicity of the eigenvalue λ (cf. Colonius and Kawan 2009). It is worth to mention that the TFE therefore coincides with the topological entropy of the uncontrolled system $x_{k+1} = Ax_k$, as defined by Bowen for maps on non-compact metric spaces (cf. Bowen 1971). However, this is a special property of linear systems and is related to the facts that (i) there is no difference between the local and the global dynamical behavior of uncontrolled linear systems and that (ii) the control sequence does not affect the exponential complexity of the dynamics, since it only appears as an additive term in the transition map of the system. Formula (1) is in correspondence with several former results on minimal data rates for stabilization of linear systems. Thinking of the definition of feedback entropy via spanning sets of control sequences, its interpretation is that in order to guarantee invariance of a bounded set, the only reason for exponential growth of the number of necessary inputs as time increases is the volume expansion of the open-loop system in the unstable subspace.

Upper Bounds Under Controllability Assumptions

If the state space of the control system is a differentiable manifold and the right-hand side is continuously differentiable, under certain controllability assumptions upper bounds for the feedback entropy can be formulated in terms of the Lyapunov exponents of periodic trajectories (for the concept of Lyapunov exponents, see, e.g., Barreira and Valls 2008) (cf. Nair et al. 2004; Kawan 2011b, 2013). More precisely, if there is a periodic trajectory in the interior of the given set K such that the linearization along this trajectory is controllable, and if complete approximate controllability holds on the interior of K (cf. Colonius and Kliemann 2000), then

$$h_{\text{fb}}(K) \leq \sum_{\lambda} \max\{0, n_{\lambda} \lambda\}, \quad (2)$$

where the sum is taken over all Lyapunov exponents λ of the periodic trajectory and n_{λ} denotes the multiplicity of λ . Using the definition of feedback entropy in terms of (τ, K) -spanning sets, one can prove this by constructing spanning sets of control functions which first steer all initial states in K into a small neighborhood of a point on the given periodic orbit and then, by use of local controllability, keep the corresponding trajectories in a neighborhood of the periodic trajectory for arbitrary future times. Similar ideas first have been used in Nair et al. (2004) to prove that the LTFE at an equilibrium is given by the sum of the unstable eigenvalues of the linearization about this equilibrium. For systems given by differential equations the upper estimate (2) can be improved under additional regularity assumptions. Assuming that the system is smooth and satisfies the strong jet accessibility rank condition (cf. Coron 1994), one can show that both assumptions, controllability of the linearization and periodicity, can be omitted. The only restriction that remains is that the trajectory must not leave a compact subset of the interior of K . However, in the case of nonperiodic trajectories, the sum of the positive Lyapunov exponents has to be replaced by the maximal Lyapunov exponent of the induced linear flow on the exterior bundle of the manifold. For control-affine systems, strong jet accessibility can be weakened to local accessibility. In general, it is unlikely that such upper bounds are tight, since they are related to very specific control strategies for making the given set invariant.

Lower Bounds, Volume Growth Rates, and Escape Rates

A general approach to obtain lower bounds of feedback entropy is via a volume growth argument, which in its simplest form works as follows. Every (τ, K) -spanning set $\mathcal{S}$ defines a cover of K , consisting of the sets (cf. Kawan 2011a, c)

$$K_{\tau, \underline{u}} = \{x \in K : \varphi(k, x, \underline{u}) \in \text{int} K,$$

$$1 \leq k \leq \tau\}, \quad \underline{u} \in \mathcal{S}.$$

It follows that $\varphi_{\tau, \underline{u}}(K_{\tau, \underline{u}}) \subset K$ and hence, since K is bounded, the volume expansion under $\varphi_{\tau, \underline{u}} = \varphi(\tau, \cdot, \underline{u})$ gives upper bounds for the volumes of the sets $K_{\tau, \underline{u}}$, which result in a lower bound for the number of these sets. For instance, the lower estimate in (1) can be established by applying this argument to the system which arises by projection of the given linear system to the unstable subspace of the uncontrolled part $x_{k+1} = Ax_k$. A refinement of this idea also leads to lower estimates of feedback entropy for inhomogeneous bilinear systems in terms of volume growth rates or Lyapunov exponents on unstable bundles, respectively. For nonlinear systems, in general only very rough estimates can be obtained by this method. However, a variation of the volume growth argument leads to a lower bound of the form

$$h_{\text{fb}}(K) \geq -\liminf_{\tau \rightarrow \infty} \frac{1}{\tau} \log \sup_{\underline{u}} \mu(K_{\tau, \underline{u}}),$$

where μ denotes a reference measure on the state space. The right-hand side of this inequality can be considered as a uniform *escape rate* from the set K , which under sufficiently strong hyperbolicity assumptions can be estimated in terms of other quantities such as Lyapunov exponents and dynamical entropies. Key references for escape rates in the classical theory of dynamical systems are (Young (1990) and Demers and Young (2006)).

Summary and Future Directions

The theory of feedback entropy for finite-dimensional deterministic systems is very far from being complete. The currently available results only give valuable information in very regular situations, and even those are not fully understood. For the further development of this theory, it will be necessary to combine control-theoretic methods with techniques from different fields such as classical, random, and nonautonomous dynamical systems. Some of the

main focuses of future research will probably be the following:

- The generalization of feedback entropy to more complex network topologies
- The formulation of a feedback entropy theory for stochastic systems
- The development of a probabilistic (resp. measure-theoretic) version of feedback entropy for both deterministic and stochastic systems, which is related to the topological version via a variational principle
- The numerical computation of feedback entropy

Abstract

The use of deep learning for sequence learning problems and system identification are intimately linked, and interesting opportunities exist on this cross section. The aim of this chapter is to briefly introduce deep learning from a system identification perspective and to explain some of the most apparent links between these two topics.

Keywords

Neural networks · Stochastic optimization · Nonlinear dynamical systems · Sequence learning · Recurrent neural networks

Introduction

Deep learning is based on the idea that when it comes to representing a function, a deep, hierarchical model can be considerably more efficient than a shallow model. While some theoretical explanations are available, the most compelling evidence is provided by all the practical applications where deep learning have changed the landscape by significantly improving the performance compared to earlier technologies in, for example, computer vision (Krizhevsky et al. 2012), speech recognition (Hinton et al. 2012), and natural language processing (Mikolov et al. 2013). While the model underlying all of deep learning – the neural network – has been around for more than 70 years (McCulloch and Pitts 1943), all recent success stories like the ones referenced above are among the key reasons for why the neural network model has yet again become so popular. Other important factors contributing to the current popularity of deep learning are massively increased datasets, availability of larger-scale compute resources, significantly improved software tools, substantial investment from industry, and finally some architectural and algorithmic innovations.

System identification is about building mathematical models of dynamic systems using observed input-output data; see, e.g., Cross-Ref ► “[System Identification: An Overview](#)”. So, system identification and deep learning are both about inferring models from observed data. This contribution is about exploring some links between the topics.

One link is that the conceptual problem structures for the two problems are quite similar. This will be exploited in sections “[The Setup and the Model Structure](#)” and “[Stochastic Optimization Is Used to Train the Model](#)”.

The other link is that system identification of nonlinear systems really amounts to estimation of a static nonlinearity in a suitable node in a signal network; see Schoukens and Ljung (2019). This means that applying deep learning to learn that nonlinearity implies that deep learning can be directly incorporated into the system identification world. This will be discussed further in

section “[Constructing Deep Learning Architectures Suitable for System Identification](#)”.

Deep Learning Background

The Setup and the Model Structure

Machine learning and deep learning are about inferring models from observed data. Such models can reproduce, if not explain, the behaviour of the system that generated the data. The core of all learning can be said to be *function estimation*, i.e., measure noisy observations of a function between two spaces $\mathcal{X}$ to $\mathcal{Y}$

$$y_t = \mathcal{F}(x_t) + \text{noise} \quad t = 1, \dots, T \quad (1)$$

and infer the function $\mathcal{F}$, where $x_t \in \mathcal{X}$ denotes the input and $y_t \in \mathcal{Y}$ denotes the output. This is like a classical curve-fitting problem, but the spaces may be of very general nature: $\mathcal{X}$ could be signals, images, texts, etc., and $\mathcal{Y}$ could be numerical values or classifications (like “text is offensive”). It is the broad range of possible spaces that allows the problem formulation to be applied to a wide variety of tasks, which is the reason for the current intense interest in the field. But for standard numerical spaces $\mathcal{X}$ and $\mathcal{Y}$, the formulation (1) remains an example of standard *nonlinear regression*. Most applications of machine learning have a *black-box* view of $\mathcal{F}$, i.e., no physical knowledge about the function is employed, and flexible mappings are used when estimating it.

This also means that the system identification perspective (see Fig. 1) can be applied to learning problems. The key elements are the method of model fitting, block $\mathcal{I}$, and the model structure $\mathcal{M}$ in that figure. For successful learning, the fitting method should allow handling large model structures with many parameters, and the model structure should be able to capture with good accuracy any reasonable function $\mathcal{F}$ that can be encountered in the application: The model structure should thus be a *universal approximator*. Section “[Stochastic Optimization Is Used to Train the Model](#)” (below) deals with optimization methods for fitting, and Section

Deep Learning in a System Identification Perspective, Fig. 1 The identification work loop. See also Fig. 4 in Cross-Ref “► [System Identification: An Overview](#)”

“[Constructing Deep Learning Architectures Suitable for System Identification](#)” deals with particular architectures for universal approximation structures used in deep learning.

But, simplistically, the bottom line is that the model for $\mathcal{F}$ can be seen as a piecewise linear, continuous function over an adaptive grid in $\mathcal{X}$. That means that the structure is defined by a number of grid points in $\mathcal{X}$, often chosen guided by the data $\{x_t, y_t\}$. The function is then defined by linear interpolation between the values at the grid points.

Such piecewise linear approximations can be created in several ways, e.g., in *regression trees*, (Breiman et al. 1984), but in machine and deep learning, the model structure is typically constructed from *neural networks* (see, e.g., Eq. (18) in the section “Nonlinear Function Estimators” in crossref “► [Nonlinear System Identification: An Overview of Common Approaches](#)”). Basically, in the simple *one-hidden-layer neural network* model, the mapping from x to y in a feedward neural network is (think of x as a scalar for simplicity)

$$y_t = \mathcal{F}(x_t) = \sum_{l=1}^m \gamma_l \kappa(\alpha_l(x_t - \beta_l)). \quad (2)$$

The so-called activation function $\kappa(z)$ can be chosen as a nonlinear function in various ways. A classical choice is the *sigmoid*

$$\kappa(z) = \frac{1}{1 + e^{-z}} \quad (3)$$

giving rise to a *sigmoidal network*. Nowadays, a dominating choice is the rectified linear unit (ReLU) function

$$\kappa(z) = \max(z, 0), \quad (4)$$

which means that the sum (2) will be piecewise linear and continuous with breakpoints in $\beta_l, l = 1, \dots, m$. The numbers $\theta = \{\alpha_l, \beta_l, \gamma_l\}_{l=1}^m$ constitute the parameterization of the model.

As in all estimation problems, the trade-off between *bias* and *variance* is crucial. See section with that name in Cross-Ref “► [System Identification: An Overview](#)”. Typically, however, this aspect is not so much stressed in most of the contemporary machine/deep learning literature. An important early contribution is Geman et al. (1992).

The bias is determined by how well the grid can approximate the function. The more grid points, the better fit is possible and the less bias. Let the number of grid points be m . The variance is determined by the number of parameters $d = \dim \theta$ that are estimated in the model structure. More parameters give higher variance. The total error in the function fit is the sum of bias (squared) and variance, so a small error results for a large m in combination with a small d . This is the crucial dilemma in function estimation.

For a simple feedforward neural network with the ReLU activation function, the number of parameters d is 3 times the number of breakpoints m . This illustrates the problem of doing advanced bias/variance trade-offs.

Deep neural networks are model structures created from simple feedforward neural networks by concatenation of the regressors in several *layers*: The m terms in (2), $x_t^{(2)} = \kappa(\alpha_l(x_t - \beta_l))$ (“the hidden units”) can be

interpreted as new regressors and be subjected to the same mapping (2):

$$y_t = \mathcal{F}(x_t) = \sum_{l=1}^{m^{(2)}} \gamma_l^{(2)} \kappa(\alpha_l^{(2)}(x_t^{(2)} - \beta_l^{(2)})), \quad (5)$$

thus giving a net with a *second layer* with $m^{(2)}$ hidden units. This can be repeated a number of times, viewing $x_t^{(3)} = \kappa(\alpha_l^{(2)}(x_t^{(2)} - \beta_l^{(2)}))$ as regressors in a third layer, etc. This is the way to create deep networks with an arbitrary number of hidden layers for the simple feedforward net. (A concrete example will be given in section “[A Case Study: The Silverbox Example](#)” below.) The specific design of a neural network is very much an art that still impacts the overall performance significantly.

A deep neural network constructed from many simple ReLU layers will still be a piecewise linear function over an adaptive grid. So what is then gained? *The point is that while the number of breakpoints will increase drastically with the depth of the net, the number of parameters will not increase at the same rate in a deep network*, so there is a potential for a better bias/variance trade-off. This of course means that there will be hidden dependencies between the breakpoints. The parameterization is so to speak less generous than the possible model flexibility. This necessitates “subroutines” in the parameterization to deal with patterns that reoccur in different parts of the function. But it also allows for the possibility to form these automatically as part of the parameter fitting process. This makes it possible to handle the bias/variance trade-off more efficiently.

Stochastic Optimization Is Used to Train the Model

To make use of deep learning, the unknown parameters θ of the underlying deep neural network model needs to be trained from data. The standard solution involves solving a non-convex optimization problem of the form

$$\hat{\theta} = \arg \min_{\theta} J(\theta), \quad \text{where}$$

$$J(\theta) = \frac{1}{T} \sum_{t=1}^T L(x_t, y_t, \theta). \quad (6)$$

The cost function $J(\theta)$ is a sum of the loss function $L(x_t, y_t, \theta)$ over all T samples in the available estimation (training) dataset. A commonly used loss function in this setting is provided by the squared prediction error, namely, $L(x_t, y_t, \theta) = (y_t - \hat{y}_t)^2$, where $\hat{y}_t$ denotes the prediction of y_t generated by the model. For classification problems, the cross-entropy loss is popular, which for two class problems is given by $L(x_t, y_t, \theta) = -(y_t \log(\hat{y}_t) + (1 - y_t) \log(1 - \hat{y}_t))$. Besides the two loss functions explicitly mentioned above, there are certainly more options (see, e.g., for Goodfellow et al. (2016) details). Due to the non-convex nature of (6), we have to resort to numerical solutions, most of which proceed in an iterative fashion according to:

1. Select an initial value θ_0 .
2. Update via a step in the search direction p_t according to

$$\theta_{i+1} = \theta_i + \gamma p_t, \quad \text{for } i = 1, 2, \dots \quad (7)$$

where the length of the step is controlled by the *learning rate* λ . A simple search direction is provided by the negative gradient direction $p_t = -\nabla_{\theta} J(\theta_t)$.

3. Terminate when a certain criterion is fulfilled and use the last θ_i as $\hat{\theta}$.

Variants of the above scheme – often with a carefully computed search direction p_t – are indeed also used in many approaches to system identification.

In most deep learning applications, the sheer size of the dataset prevents us from evaluating the cost function (6) and its derivatives using all the data at the same time. Instead, the estimation dataset is partitioned into many smaller sets, so-called *mini-batches* typically containing $n_b=10$,

$n_b = 100$ or $n_b = 1000$ data samples each. The model is then trained according to a scheme similar to the one above on each mini-batch. Since we are only using a small part of the dataset for each mini-batch, the values we obtain for the cost function and its derivatives are merely estimates of the corresponding true values, implying that we are now in fact faced with a stochastic optimization problem.

We transition from one mini-batch to the next by using the estimate from the current mini-batch as initial value for the next mini-batch. The resulting estimates are indeed noisy, and there are elaborate techniques – referred to as noise reduction – for averaging these values to compute a final point estimate (see Bottou et al. (2018) for a recent overview). These noise reduction approaches work well in practice, and they can also be analyzed theoretically. The n_b samples constituting each mini-batch are typically drawn at random, often implemented by a random shuffle of the estimation data before dividing it into mini-batches. One complete pass through the estimation data is called an *epoch*. The stochastic optimizers used are often improved developments of the classic Robbins-Monro stochastic approximation algorithm (Robbins and Monro 1951). A good contemporary introduction is provided in Bottou et al. (2018), clearly showing that stochastic optimization is currently a very active research problem due to its importance in deep learning and other large-scale machine learning problems. It is also worth mentioning that the structure of the neural network should be exploited – via the chain rule and reuse of information – in computing the gradient, which is known as backpropagation (Williams et al. 1986).

Constructing Deep Learning Architectures Suitable for System Identification

Using the language of machine learning, the system identification problem is a so-called *sequence learning* problem, where the task is to learn a model for data arriving in a sequential fashion. We will in this section provide a very

brief overview of current trends when it comes to suitable deep learning models for system identification.

There exist a multitude of deep learning models specifically tailored for sequence learning. The classic example is the recurrent neural network (RNN) (Williams et al. 1986), which has an internal hidden (deterministic) state h_t – akin to a state space model – allowing an RNN to model temporal sequences. The RNN is described by the following dynamical model

$$h_t = f_\theta(x_t, h_{t-1}), \quad (8a)$$

$$y_t = h_\theta(x_t, h_t), \quad (8b)$$

where f_θ and h_θ are deterministic nonlinear functions and θ denotes the parameters governing them. Note that this is closely related to the standard nonlinear state space model. While the information flow in a deep feedforward neural network is fairly straightforward, this is not the case for an RNN, in which feedback effects must be considered; an informative exploration of this topic is available in Pascanu et al. (2014).

There are three basic ways in which we can construct a deep RNN, namely, in using deep models to describe the hidden-to-hidden transition (h_{t-1} to h_t), the input-to-hidden transition (x_t to h_t), and finally the hidden-to-output transition (h_t to y_t). The key difference is that in a feedforward neural network, the information flows from the input x_t sequentially through the network to the output y_t , whereas in an RNN, the information travels in *loops* through the network. This implies that information that is fed into an RNN can stay in its memory (via the hidden states h_t) for an extended period of time, recall (8).

Two popular extensions of the RNN are the long short-term memory (LSTM) (Hochreiter and Schmidhuber 1997) and the gated recurrent unit (GRU) (Cho et al. 2014). These architectures are specifically designed to remember information about states in the more distant past, often referred to as long-term dependencies. If the underlying phenomenon is Markovian, then we know that the current state is all we need in predicting the future and the basic RNN (8) is all

we need. However, there are many phenomena that are non-Markovian, implying that we also need information about states in the more distant past, often referred to as long-term dependencies, in which case the basic (possibly deep) RNN is not enough. The LSTM and the GRU are specifically designed for learning these long-term dependencies.

It has also been shown (Bai et al. 2018) that variations of the popular convolutional neural network (CNN) is highly effective for problems with sequential structure. A CNN can be described as a regularized version of a multilayer perceptron, often used in image processing. See Andersson et al. (2019) for some initial investigations of the use of CNNs for nonlinear system identification.

This is not the place for introducing these deep neural network models in detail, but it is important to note their shared key characteristics, namely, the deep neural networks ability to *automatically* extract highly useful features from the raw data. This is the reason for the name *end-to-end learning*, since it alleviates painful manual preprocessing of the data. For many applications of deep learning, it is indeed so that manual intervention degrades the overall performance. This automatic feature extraction is intimately linked to the fact that – as was mentioned above – patterns recurring in different parts of the function are handled more efficiently. A problem

inherent in deep neural networks is that they do not encode much structural knowledge and this is where classical system identification models become interesting and useful.

Classical models employed in solving system identification problems include, for example, autoregressive (AR), autoregressive moving average (ARMA), Box-Jenkins (BJ), and the state space model (SSM). A straightforward merger of the deep learning models and these classical model structures involves simply representing the unknown functions with a deep neural network. For example, in the case of a nonlinear AR model where $y_t = f(y_{t-1}, y_{t-2}, \dots, y_{t-n_y}) + e_t$ and e_t describes the noise, the function f can be encoded using a deep neural network. However, there is currently a clear trend towards more elaborate mergers of these models. One natural idea that remains active is to augment the deterministic RNN (8) with a latent *random* variable (Boulanger-Lewandowski et al. 2012; Osendorfer and Bayer 2014; Fabius et al. 2014; Chung et al. 2015; Rangapuram et al. 2018). In this way the model gains additional expressiveness in that it can now also make use of – carefully designed – random noise in explaining the available measurements. As one concrete example, we mention the construction offered by Rangapuram et al. (2018), involving a deterministic RNN where each hidden state feeds into the parameters of a state space model.

Deep Learning in a System Identification Perspective, Fig. 2 The Silverbox data. Left: estimation data, Right: validation data

A Case Study: The Silverbox Example

A data set that has often been used as a nonlinear test case is the so-called Silverbox example. This is a forced Duffing oscillator that is an electronic circuit that mimics a mechanical system with a cubic hardening spring. The experiment is described in Schoukens et al. (2016), and the data is available on www.nonlinearbenchmark.org/#Silverbox. Two sets of data were collected with different excitations, depicted in Fig. 2. The

estimation data are used to fit a model, and the validity of the model is checked by how well it reproduces the validation data. That is, the model is simulated using the validation data input, and the discrepancy between model output and measured validation data output is determined. This is a standard system identification task.

To load the estimation and validation data, the following MATLAB sequence can be used (files obtained from the website above)

```
load SNLS80mV.mat
fs = 1e7/2^14;
edat = iddata((V2(30550:38500)', V1(30550:38500)', 1/fs)
load Schroeder80mV
ySchroeder = V2(10585:10585+1023);
uSchroeder = V1(10585:10585+1023);
vdat=iddata(ySchroeder', uSchroeder', 1/fs);
```

Note that the validation data (essentially swept sinusoids) have a quite different character from the estimation data (random phase multisines). This means special demands for the model to pick up essential features in the generation of the output – not only to reproduce observed output behavior.

To check models, first estimate a common linear, so-called Box-Jenkins model (see, e.g.,

Chapter 4 in Ljung 1999) with four poles, four zeros, and a second-order noise transfer function

```
mbj=bj(edat, [4 4 2 2 0]);
```

The accuracy of this model on validation data is computed by

```
[ys, Fit]=compare(vdat, mbj)
Fit = 29.71 % (percent of the output variation reproduced
              by the model)
```

A sigmoidal one layer neural network (2) and (3) model with $m = 36$ hidden nodes is estimated and validated by

```
mnn = nlarx(edat, [4 4 0], sigmoidnet('NumberOfUnits', 36));
[ys, Fit]=compare(vdat, mnn)
Fit = 60.04
```

A deep learning model (5) with six layers of cascaded feedforward nets with six nodes each is estimated and validated by

```
net=cascadeforwardnet([6,6,6,6,6,6]);N2=neuralnet(net);
mN2=nlrx(edat,[4 4 0],N2);
[Ys, Fit] = compare(vdat,mN2)
Fit = 99.30
```

The example (that uses MATLAB's system identification and deep learning toolboxes) illustrates a number of things:

- Deep learning for modeling dynamic systems can be approached very much like a conventional system identification problem with the same type of syntax.
- The deep model shows considerable advantages compared to linear models and conventional neural network models with the same number of nodes.

Summary and Future Directions

Deep learning has transformed several scientific fields, but it has so far reached surprisingly little traction within the field of system identification. We believe that this is about to change, and with this chapter, we have tried to establish a common ground for bringing the two areas closer to each other. As concrete ideas for how to make this happen, we end by outlining a few ideas for future work.

The current system identification working cycle involves a fair bit of pre-processing work by the engineer. While the deep learning models also need certain pre-processing, they offer a highly interesting and remarkable ability of learning complex patterns automatically from raw data. This capability is indeed the key reason for the recent success of deep learning. There are interesting possibilities in exploiting these capabilities in system identification problems involving large datasets. Secondly, we recall the possibilities of combining deep learning architectures with standard models of system identification, like the state space model. This represents an active strand of research, and there are several constructions available already (see, e.g., Boulanger-Lewandowski et al. (2012),

Osendorfer and Bayer (2014), Fabius et al. (2014), Chung et al. (2015), and Rangapuram et al. (2018)). Inspired by the initial success of these constructions, we believe that there is more to be understood here and more models to be explored. Thirdly, we mention the possibility of making use of theoretical tools from systems theory to help understand why deep learning works so well and to establish fundamental properties describing deep learning. This is also likely to be a fruitful path for developing new and improved stochastic optimization techniques to be used in training deep neural networks. Finally, we end by calling for thorough case studies on real-world data, where the new deep learning models are compared to more traditional system identification approaches.

Recommended Reading

There is by now a massive amount of literature of various aspects of deep learning, and it is almost impossible to get a grasp of it all. However, a good starting point is provided by the executive summary provided in LeCun et al. (2015). For a more thorough starting point, the textbook (Goodfellow et al. 2016) is a good option. The literature on deep learning for system identification is still rather scarce, but if we consider the more general topic of sequence learning, there are a lot of interesting developments available (see, e.g., Boulanger-Lewandowski et al. (2012), Osendorfer and Bayer (2014), Fabius et al. (2014), Chung et al. (2015), and Rangapuram et al. (2018)) to get started.

Abstract

Demand-responsive electric loads respond to prices or other signals sent by the electric utility or power system operator by decreasing consumption (shedding) and/or shifting load in time. Demand response provides a variety of technical and economic benefits to the grid, usually causing minimal inconvenience to consumers. Traditionally, demand response has been used to decrease system-wide peak consumption. In that case, demand response events are called rarely and seek to achieve

large changes in load. Today, demand response is also used to provide a variety of other services to power systems. In some cases, loads are expected to respond continuously while still meeting the needs of consumers. In this article, we describe the types of loads well-suited to demand response and their response methods, typical demand response program designs and control methods, and emerging applications of demand response.

Demand response · Electric loads · Peak load shedding · Ancillary services

Introduction

Many parts of the world have shifted to using electricity markets to transact electrical energy and reliability services, instead of letting monopolistic vertically integrated utilities decide how best to match demand with supply. However, these markets are usually one-sided in that electric power generation companies compete to sell power (supply), but electric load (demand) is nonresponsive to market forces, i.e., inelastic. Demand response is an attempt to make electric load elastic. It is defined by the US Federal Energy Regulatory Commission (FERC) as “changes in electric usage by demand-side resources from their normal consumption patterns in response to changes in the price of electricity over time, or to incentive payments designed to induce lower electricity use at times of high wholesale market prices or when system reliability is jeopardized” (Federal Energy Regulatory Commission 2019). These changes include net reductions in energy usage through *shedding*, especially during times of system-wide peak consumption, or through energy-neutral *shifting*.

Demand response can reduce wholesale electricity market prices and their volatility, improve power quality and system reliability, defer the need for grid infrastructure investments, and support the integration of fluctuating

renewable energy resources such as wind and solar by shifting load to better match production. While various forms of demand response have been used since the creation of the first power networks (e.g., time-of-use electricity pricing, load curtailment), demand response programs are currently expanding in size and scope, aided by lower-cost sensing and communication systems that enable faster and more accurate responses that provide more value to the power grid.

Demand-Responsive Loads and Response Strategies

A variety of residential, commercial, and industrial/other loads can provide demand response.

Residential

Many utility companies offer demand response programs to residential customers with air conditioning or electric heating systems, which can be switched off or cycled less frequently during times of system-wide peak consumption. These loads can also be shifted in time through pre-cooling/preheating strategies. Other residential loads such as dishwashers, clothes washers and dryers, and electric vehicles need to consume a certain amount of energy to perform their function, but the exact timing of their power draws is flexible; these loads can be deferred. For example, electric vehicles can be charged in the middle of the night, instead of immediately upon plug-in.

Commercial

Commercial building heating, ventilation, and air conditioning (HVAC) systems can be controlled to provide demand response. Motegi et al. (2007) list ten strategies including adjusting room temperatures, limiting fan variable-frequency drives, and adjusting chilled water temperatures. These strategies are useful for load shedding, and some are useful for load shifting. Lighting levels can also be modulated for demand response; however, unlike heat which can be stored, light cannot, and so lighting control is only suitable for load shedding, not load shifting.

Industrial/Other

Industrial processes can be scheduled to leverage flexibility in the timing of electricity-consuming steps and used for demand response. For example, Mathieu et al. (2011) analyze the data from an industrial-scale bakery that schedules pan washing to avoid times of system-wide peak consumption. Some industrial processes, such as aluminum smelting, can be modulated to provide load shifting in response to real-time signals from the power system (Todd et al. 2009). Electric pumping in agricultural systems, drinking water transport systems, and water treatment systems can be shifted in time to provide demand response.

Demand Response Programs

There are a number of taxonomies classifying demand response programs, e.g., Albadi and El-Saadany (2008). Here we split programs into three types: price-based, incentive-based, and market-based.

Price-Based

Price-based programs illicit a response by sending time-varying electricity prices to consumers, encouraging them to reduce consumption when prices are high (and, possibly, increase consumption when prices are low). Time-of-use prices follow a schedule known to consumers, while dynamic prices change over time in response to electricity market conditions (or proxies for those conditions like outdoor air temperature, which affects system-wide load and wholesale prices). There are a large variety of dynamic pricing designs including peak prices, where prices surge a small number of days/times per year, and real-time prices directly tied to wholesale electricity market prices.

The *utility's problem* is to design prices to achieve system cost and reliability goals while considering the impact on consumers. In practice, electricity rates must be approved by regulatory bodies responsible for protecting consumers. The *consumer's problem* is to respond to electricity prices. If they are known in advance

(e.g., time-of-use prices), a consumer could solve a multi-period optimization problem to minimize their energy costs subject to constraints capturing the flexibility of their electric loads. Responding to real-time electricity prices is more difficult; in practice, consumers often apply threshold policies to switch on/off loads if prices go below/above certain thresholds.

Incentive-Based

Incentive-based programs illicit a response by providing incentives, usually payments or electricity bill reductions, for demand response program participation and/or actions. For example, some utilities offer demand response programs that pay consumers for shedding load during times of system-wide peak consumption. Load sheds are computed by comparing actual load to an estimate of what the load would have been without demand response, known as a *baseline*. A variety of methods exist for estimating baselines including averaging historical load profiles and regression models built from historical data.

Some incentive-based demand response programs require consumers to sign a *contract* with the utility or a third-party company offering services to the utility or the power market operator. The contract defines the demand response actions, constraints, and payments. For example, for a consumer participating in an air-conditioning cycling program, the action could be utility-controlled air conditioner cycling on up to 12 hot summer days/year, the constraint could be the ability of the consumer to override cycling when indoor temperatures deviate more than 3°C from normal, and the payment could be based on program participation and/or on the number of days the air conditioner is actually cycled.

The *utility's problem* is to design incentives (or contracts including incentives) to achieve system cost and reliability goals while considering the impact on consumers. The *consumer's problem* is to use their load flexibility to maximize their incentives (or to choose the contract that maximizes their incentives) while ensuring that their electricity needs are met.

Market-Based

Market-based programs are similar to price-based programs in that consumers respond to time-varying electricity prices; however, in market-based programs, consumer actions impact price formation. Specifically, consumers or third-party companies acting on behalf of groups of consumers provide demand curves specifying their load as a function of the electricity price. The market operator collects all of the demand curves from the loads and supply curves from the generation companies to clear the market and determine electricity prices. Consumers respond to prices according to their demand curves. While price-based programs are simpler, they may lead to load synchronization and price oscillations (Callaway and Hiskens 2011). Market-based programs can mitigate these issues, but not completely eliminate them.

The *market operator's problem* is to design the market to maximize social welfare. The *consumer's problem* is to design their demand curve to minimize their energy costs considering their electricity needs and the flexibility of their electric loads. Game theoretic approaches have been used to study this problem.

Emerging Applications

Responsive demand is now providing a variety of services to power systems, and researchers continue to investigate new demand response applications and load coordination architectures that are well beyond the scope of the FERC demand response definition. Here, we describe three emerging applications.

Load Coordination for Balancing Reserves

Power system operators procure balancing reserves to correct differences in electricity supply and demand on timeframes of seconds to minutes. Traditionally, balancing reserves are provided by fast-acting generators, like natural gas power plants, that operate below their maximum output level, enabling them to decrease and increase power production as load decreases and increases. Loads can also

supply balancing reserves by increasing and decreasing power consumption with respect to their baseline, ideally through load shifting. For example, the power consumption of thousands of residential air conditioning systems can be coordinated to provide frequency regulation (also known as secondary frequency control). A key challenge is to design a coordination scheme that produces accurate responses, is non-disruptive to customers, and is low cost in terms of both infrastructure and operational costs. The problem can be formulated as a real-time control problem, and researchers have investigated reduced-form dynamical system modeling, state estimation to reduce sensing/communication needs, and control design for large-scale, uncertain, nonlinear systems. Some strategies have been piloted and deployed in practice. This application is best achieved through incentive-based demand response programs with contracts.

Distribution Network Upgrade Deferral

Addition of more large loads such as electric vehicles and distributed generation such as solar photovoltaics to electricity distribution networks stresses the network and can lead to a variety of problems including low/high voltages and transformer overloading. Rather than upgrade these networks with new equipment, demand response can be used to mitigate these problems, deferring upgrades and reducing costs. For example, electric vehicles themselves could participate in demand response mitigating their own impacts, or other loads like residential air conditioning systems and commercial HVAC systems could support electric vehicles and/or solar photovoltaics. Price-based or incentive-based demand response programs could be used to achieve this application, though incentive-based programs with contracts would achieve more reliable responses and, subsequently, a more valuable service.

Maximizing Self-Consumption of Solar Power

Some countries use feed-in tariffs for residential solar photovoltaic generation. Specifically, consumers are paid for each kWh fed into the grid.

When the feed-in tariff is lower than the price of electricity, it encourages consumers to maximize self-consumption of the solar power they produce, which can be achieved by load shifting. No demand response program is necessary; the solar pricing policy drives demand response actions.

Summary and Future Directions

This article provided an introduction to demand response including an overview of demand-responsive loads, demand response program designs, and emerging applications. It highlighted various optimization and control problems corresponding to different program designs and applications. It also emphasized that demand response is much broader than peak load management. Responsive loads can provide a large variety of services to the electric power system, and some of these services may become particularly valuable in power systems with significant penetrations of fluctuating renewable energy resources.

Future directions include the development of additional demand response applications (services and value streams) and load coordination architectures that better balance technological, economic, social/behavioral goals and constraints.
